or with molecules (Equation 5):

\[ A^* + BC \rightarrow A + BC^* \]  

(5)

Depending on the experimental conditions used, some of these quenching processes can significantly affect the fluorescence radiance.

### 1.4 Interferences

As with atomic absorption spectroscopy (AAS) and AES methods, interferences of two major types are encountered in atomic fluorescence. Spectral interferences arise when lines in the source overlap lines of the matrix elements in the atomizer. Chemical interferences result from various chemical processes during atomization that reduce the population of free atoms.

Spectral interferences are seldom caused by line sources, but may be a problem with nondispersive instruments or in dispersive apparatus with continuum sources. Since generally there are several fluorescence lines available, it is sometimes necessary to select different lines to avoid the spectral interference. Chemical interferences caused by matrix components are one of the major problems in atomic fluorescence. This type of interference can be reduced by introducing different chemicals into the matrix, such as releasing agents and protective agents. Coupling to vapor generation can also significantly reduce the problem.

### 2 INSTRUMENTATION

The basic layout of an AFS instrument is similar to those for AAS and AES except that the light source and the detector are located at a right-angle. A schematic diagram of an AFS instrument is shown in Figure 2. Although the configuration of an AFS instrument can be modified for different purposes, the basic apparatus consists of a radiation source, an atomizer, a wavelength-selection system, a signal detector, and an electronic readout system.

![Schematic diagram of an AFS instrument](image)

**Figure 2** Schematic diagram of an AFS instrument.

#### 2.1 Excitation Sources

A number of excitation sources have been used in AFS and can be categorized into two types, spectral line sources and continuum sources. Since the intensity of the fluorescence radiance is proportional to the intensity of the exciting radiation, sources with high radiance are required in order to achieve a good sensitivity and linear range. Indeed, a major part of the effort devoted to improvement of AFS instrumentation in recent years has been concerned with the excitation source. Winefordner discussed the criteria of importance in choosing excitation source for AFS and provided some general considerations. Briefly, in addition to a high radiance over the absorption line (in order to obtain a good detection limit (DL) and linear range), the source should have good short- and long-term stability. In view of the need for convenience and ease of use, the source used should also require a minimum of maintenance and adjustment to obtain optimum performance. Only the most commonly used and recently developed sources are discussed here.

##### 2.1.1 Hollow-cathode Lamps

Although the conventional, and commercially available, hollow-cathode lamp (HCL) is the most widely used line source used in AAS, the early version of the HCL did not show impressive potential as a useful radiation source for AFS because it does not possess sufficient intensity. Different efforts have been made to improve the design of HCLs. For instance, the lamps can be operated using short-duration pulses of current with a sufficient off-period between pulses to maintain the mean lamp current at a low level. The pulsed lamps provide an increase in peak intensity and a reduction of the total signal observation time. Compared with regular HCLs, good results have been obtained with pulsed HCLs for a large number of elements.

The boosted discharge hollow-cathode lamp (BDHCL), or boosted output HCL as it is sometimes called, produces intense spectra with narrow line widths and can be manufactured to provide an excellent source for many elements. Since its introduction as an AFS excitation source by Sullivan and Walsh, it has received a great deal of attention and a number of modifications to this type of source have been made. Recently, BDHCLs have become commercially available and this contributed significantly to the availability of commercial AFS instruments.

The operation principle of the BDHCL is illustrated in Figure 3. The lamp consists of an anode mounted behind a cylindrical cathode. A primary discharge is struck between the cathode and anode to sputter atoms of the element of interest, as in a normal...
Electrodeless discharge lamps (EDL) are useful sources of atomic line spectra and provide radiant intensities that are usually one or two orders of magnitude greater than the normal HCLs. This type of lamp has been widely employed for AFS. A typical lamp is constructed from a sealed quartz tube containing a few torr of an inert gas such as argon and a small quantity of the metal of interest (or its salt). The lamp does not contain an electrode but instead is energized by an intense field of radio frequency or microwave radiation. Radio and microwave frequency electromagnetic fields are very efficient for generating and accelerating electrons and thereby maintaining a gaseous glow discharge without internal electrode contact with the plasma.

The characteristics of EDLs have been studied and discussed in some detail. Useful recommendations have been given by Van Loon to predict lamp behavior and to select operating conditions for the EDLs for AFS. The main drawbacks of the EDLs are their high concentration broadening and line broadening.

2.1.3 Xenon Arc Lamps

High-pressure xenon arc lamps, producing a stable and intense continuum source, have been commercially available for many years. The lamp produces intense radiation by the passage of current through an atmosphere of xenon. The spectrum is continuous over the range 250–600 nm, with the peak intensity about 500 nm. The advantage of this type of continuum source is that it can be readily employed for multielement analysis along with the use of a monochromator or interference filters. However, its intensity falls off severely below about 210 nm, thus making it unsatisfactory for the analysis of some environmentally important elements such as arsenic and selenium.

2.1.4 Laser Sources

Lasers have become important sources in analytical instrumentation because of their high intensity and narrow bandwidths and the coherent nature of their outputs. As a consequence of these unique properties, laser-induced fluorescence (LIF) offers a very sensitive and selective spectroscopic method, which has a low susceptibility to spectral interferences. Compared with conventional light sources, laser excitation also allows nonresonance transition lines to be used for many elements, which significantly reduces any laser radiation scattered off the vaporized sample.

LIF has been used for the determination of many elements in a variety of samples, including environmental matrices. The most sensitive DLs that have been reported have been as low as a few attograms. The basic requirements for the laser include wavelength tunability across the ultraviolet (UV) and visible spectrum to allow for the determination of as many elements as possible. The most commonly used LIF is the pulsed excimer- or yttrium aluminum garnet (YAG)-pumped tunable dye laser because it provides sufficient peak energy and wavelength tunability. However, this type of source has some drawbacks, such as the need to replace the dry solution, which is often toxic and flammable, before a wavelength change of more than 20–30 nm, and dye degradation with time. These disadvantages have significantly limited the application of this type of laser source to routine sequential multielement analysis. Research has been conducted to find alternatives to the pulsed dye laser. Recently, Zhou et al. reported a pulsed (10 Hz) optical parametric oscillator (OPO) laser system based on β-barium borate crystals and equipped with a frequency-doubling option for use in LIF. This all-solid-state laser has a narrow spectral line width and wide spectral tuning range (220–2200 nm). It has been used for cobalt, copper, lead, manganese, and thallium analysis in Buffalo River sediment samples.

The production of far-UV radiation is required for excitation of some elements, such as arsenic at 193.70 nm and selenium at 196.03 nm. With the availability of β-barium...

atoms in the optical path, low quenching properties, low
cost of operation, and ease of handling. The quenching
process is especially important for AFS and has been
taken into consideration in the design of the atomizer.
The order of quenching efficiency for some gases is
atomization at such low temperature (about 800 °C,
reduced quenching cross-section.
Flame emission and the associated flame flicker noise
considerably increase the limits of detection in AFS.
Flames with low background emission are therefore
necessary. Diffusion flames, sometimes called cool flames,
were developed and used for this purpose. The term
diffusion flame is generally applied to flames in which
the oxidant necessary for combustion is fully supplied
by diffusion and/or entrainment from the surrounding
atmosphere.\(^\text{(1)}\) Argon is generally used as carrier gas and
hydrogen is used as fuel gas. The temperature of these
argon–hydrogen–air flames ranges from 280 to 850 °C,
depending on the flame region selected. Despite the rela-
tively low temperature achieved by these flames, they are
still widely used as efficient atomizers for the analysis of
some environmentally important elements. Indeed, a very
simple atomizer based on an argon–hydrogen diffusion
flame has recently been employed in a commercially
available AFS system for hydride-forming elemental
analysis.\(^\text{(12)}\) The argon–hydrogen diffusion flame used
emits very low background radiation over the wavelength
region of interest, and the hydride compounds are easily
decomposed in such a low-temperature flame. In addition,
the quenching effect is relatively low in theargon-
supported flame and in hydrogen.
Different designs of diffusion flame atomizers have
been proposed and studied.\(^\text{(12,29–32)}\) A simple glass or
silica tube (i.d. 4–8 mm) has been used to support the
argon–hydrogen flame.\(^\text{(31)}\) Corns et al. recently investi-
gated four different types of diffusion flame atomizers
for arsenic analysis using hydride-generation/atomic flu-
orescence spectroscopy (HG/AFS) technique.\(^\text{(12)}\) From
this comprehensive study, they concluded that the
AFS signals were observed only in the presence of
argon–hydrogen flames. The attempt to achieve atomiza-
tion using an electrically heated atomizer alone, without
an argon–hydrogen diffusion flame, failed. These results
provided further evidence to support the atomization
mechanism proposed by several workers.\(^\text{(1,33–36)}\) The
atomization at such low temperature (about 800 °C) is
not due to thermal decomposition, but to free radicals in
the flame.

2.2.2 Electrothermal Atomizers
Although the flames discussed above are very conve-
nient and have been widely used as atomization cells
in AFS, they do have disadvantages for some analyti-
cal work. The high dilution of the sample by flame
gases limits the atom concentration attainable. The large
sample requirement with continuous nebulization makes

2.2 Atomizers
Many atomizers used for AFS are similar to those
used for AAS and AES. The design and properties of
these atomizers have been discussed comprehensively
in terms of their applications for AFS.\(^\text{(1–3,7)}\) The basic
requirements of an atomizer for AFS are an efficient
and rapid production of free atoms with minimum
background noise, long residence time of the analyte
atoms in the optical path, low quenching properties, low
cost of operation, and ease of handling. The quenching
process is especially important for AFS and has been
taken into consideration in the design of the atomizer.
The order of quenching efficiency for some gases is
Ar < H\(_2\) < H\(_2\)O < N\(_2\) < CO < O\(_2\) < CO\(_2\).\(^\text{(28)}\) A number
of atomizers have been developed and used for AFS, and
some improvements have been made in recent years.

2.2.1 Flame Atomizers
Perhaps the most commonly used flame atomizer\(^\text{(5,7)}\)
in early studies was a premixed laminar flame with
inert gas sheaths. Without using inert gas sheaths, the
premixed laminar flame, in particular the acetylene-based
flame, exhibits high background emission due to radicals
present in the secondary reaction zone (OH, C\(_2\), CH,
CN) resulting in poor DLs. By preventing entrainment
of the surrounding atmosphere into the flame gases,
the secondary reaction zone may be shifted away from
the primary reaction zone, thus extending the region of
interconal zone, which is the most used part of the flame
for spectroscopy. Separation of the secondary reaction
zone can be effected using either nitrogen or argon. Argon is favored over nitrogen because of its greatly
reduced quenching cross-section.

Flame emission and the associated flame flicker noise
can be isolated with suitable absorption or interference
filters. The mercury lamp has been used in commercially
available instruments with a 254-nm filter for mercury
analysis.\(^\text{(27)}\)
it unsuitable for small-volume sample analysis, and the
flame cells are not convenient for the direct atomization
of solid samples. Precise control over the chemical envi-
ronment in the flame is impossible. These drawbacks of
the flame atomizer can be overcome by using electrother-
mal atomization (ETA) techniques. These electrothermal
atomizers are designed in different shapes and are gener-
ally made of graphite. Graphite atomizers are operated
at high temperature and the atoms are contained in an
inert gas atmosphere. This provides a high atomization
efficiency and reduced quenching, consequently offering
high sensitivity for small volumes of sample. It has been
suggested that the most successful atomic atomizer for
LIF spectrometry is the graphite furnace.\(^{(19)}\)

LIF coupled with ETA has been one of the main
research fields for many scientists in the past two
decades.\(^{(19,20,22-24,37-40)}\) The development of electrother-
amal atomizers used for AFS benefits greatly from the
alanalytical knowledge accumulated over the years with
the well-established atomic absorption technique. Gen-
erally, certain modifications of the conventional graphite
furnaces are required if they are to be usable in LIF.
The optical detection of fluorescence needs to be made at
90° with respect to the excitation axis. The following are
the typical forms of the graphite furnace studied for AFS:
graphite cup,\(^{(37)}\) Massmann cup,\(^{(41)}\) graphite rod,\(^{(42,43)}\) and
graphite tubes.\(^{(38,39)}\) There seems to be a general consen-
sus that graphite-tube atomization is preferable to other
graphite atomization techniques,\(^{(39)}\) and it has been used
in most of the later studies.\(^{(19,20,22)}\) With graphite-tube
atomization, the atoms are contained in a hot environ-
ment while being excited by the laser, and therefore much
better analytical performance can be achieved.

Besides examining a variety of designs and shapes
for the furnace, other studies, such as those atomizing
at a pressure-controlled\(^{(20)}\) and pyrolytically coated\(^{(44)}\)
graphite atomizer, have also been conducted to improve
the performance of these furnaces. The use of low-
pressure vaporization to remove matrix interferences
associated with the analysis of solid samples has been
coupled with laser-induced fluorescence/electrothermal
atomization (LIF/ETA).\(^{(45)}\) A lower DL was found by
using the low-pressure vaporization technique. Using a
coating on graphite furnaces was initially conducted in
ETA in the AAS technique to inhibit reaction between
the analyte and the graphite.\(^{(46)}\) Among the different
coating methods used for the graphite atomizer in AFS,
a pyrolytic coating has been the most popular.\(^{(19,20,38)}\)

### 2.2.3 Cold-vapor Technique for Mercury

Mercury is the only metallic element that exhibits an
appreciable atomic vapor pressure at ambient tempera-
ture. The mercury has a vapor pressure of 0.0016 mbar
(1 mbar = 10\(^2\) Pa) at 20 °C, corresponding to a concen-
tration of approximately 14 mg m\(^{-3}\) in air.\(^{(46)}\) This unique
property gives rise to the possibility of measuring mer-
cury without the additional thermal energy supplied by a
flame or electrothermal heating. The cold-vapor atomic
absorption spectrometry (CVAAS) technique for mer-
cury analysis has been studied extensively. This method is
readily applicable to AFS [cold-vapor atomic fluorescence
spectrometry (CVAFS)]. Briefly, the mercury vapor, pro-
duced by reduction of the metal from its compounds
with suitable reductants [sodium borohydride or tin(II)
chloride], is swept out of the reaction vessel using argon
carrier gas and introduced into the optical beam where
the mercury atoms can be excited with a suitable source.

#### 2.2.4 Miscellaneous Atomization Techniques

The inductively coupled plasma (ICP) has been proposed
as an atomizer for AFS.\(^{(47,48)}\) Plasmas have better
vaporization and atomization efficiency than flames
and give less interference problems. Within an argon
atmosphere, ICP is characterized by a high fluorescence
yield because of the small quenching cross-section.
Background emission is dependent on the viewing region
but is generally higher than in flame.\(^{(28)}\) Although the
ICP shows some advantages as an atomizer, the high cost
compared with flame and electrothermal atomizers has
discouraged its widespread application to routine AFS.

The atomization of an analyte can be also carried out
on the principle of an HCL in which the sample is vapor-
ized by a glow discharge.\(^{(46)}\) Recently, a microsecond
pulsed glow discharge was studied as an analytical spec-
trosopic source for solid-sample analysis.\(^{(49)}\) The results
showed enhanced efficiency for analytical response of the
sputtered sample atoms.

### 2.3 Wavelength Selection and Detection Systems

The simplicity of atomic fluorescence spectra makes the
isolation and detection of the selected atomic fluorescence
lines easier than in other atomic spectrometric techniques
such as AAS and AES. Both a monochromator and an
interference filter have been used as wavelength selectors
with different advantages and limitations. The require-
ments for wavelength selection depend on the light source
employed. With conventional line sources (HCL, EDL)
or laser excitation, low-dispersion monochromators or
nondispersive systems can be used. The nondispersive
instruments are simple and cheap, and readily adapt-
able to multielemental analysis. They also have a high
energy throughput and thus high sensitivity.\(^{(10)}\) However,
to realize these advantages, it is necessary that the output
of the source is free of contaminating lines from other
elements, and no significant background radiation should
occur. In most of the instruments, a filter located between
the source and detector has been used to remove background radiation. With a continuum excitation source, a dispersive system is required to discriminate against the scattering of source radiation and the fluorescence radiation from other species over the entire ultraviolet/visible (UV/VIS) region.\(^{28}\)

Fluorescence radiation is usually detected with a photomultiplier tube (PMT) as in many other spectrometers\(^ {7,10}\). The PMTs are highly sensitive to UV and visible radiation and have extremely fast response times.

Since the wavelength selection and detection systems used in AFS are similar to those of AAS and AES, readers are referred to other comprehensive discussions in the literature\(^ {10,46}\). Over the years, a number of AFS instruments have been developed, and have either been used exclusively in research laboratories or have only recently become commercially available. To the author’s knowledge, AFS instruments for the analysis of mercury and some other elements are currently being manufactured by three companies: P. S. Analytical Ltd, Sevenoaks, Kent, UK, Brooks Rand Ltd, Seattle, WA, USA, and Tekran Inc., Ontario, Canada. Different features of these instruments will be discussed in the following sections along with their applications in environmental analysis.

## 3 ENVIRONMENTAL APPLICATIONS

### 3.1 Mercury

Mercury pollution has become a global problem because of its wide occurrence in the environment. The toxicological effects of mercury compounds on environmental systems have long been recognized. Therefore, mercury monitoring is a special concern in the field of heavy metal analysis. AFS-based techniques have been widely used in environmental analysis. The resonance fluorescence line at 253.7 nm (\(^{3}\)P\(_{1}\) – \(^{1}\)S\(_{0}\) transition) has been generally used in most atomic fluorescence studies on mercury. AFS instruments are now commercially available for both total mercury and organomercury species analysis.

#### 3.1.1 Total Mercury

##### 3.1.1.1 Instrumentation

Traditionally, CVAAS has been the most commonly used method for determining mercury at trace levels. This technique has been well established and several commercial systems are available.\(^ {46}\) CVAFS was proposed almost three decades ago as a method for mercury analysis.\(^ {50–52}\) The advantages of AFS over AAS, in terms of sensitivity, linear range, and spectral interferences, have been demonstrated both theoretically\(^ {53}\) and experimentally\(^ {50,54}\). However, it was only during the beginning of the 1990s that AFS became commercially available.\(^ {55,56}\) AFS detection, especially coupled with the vapor generation technique, is becoming popular and replacing AAS for mercury analysis in many research and service laboratories owing to its unique sensitivity, specificity, and simplicity.

Similarly to CVAAS, a general CVAFS system consists mainly of two parts, the mercury vapor generator and the AFS detector. A schematic diagram of a continuous-flow vapor generator is shown in Figure 4.\(^ {27}\) The reductant, blank (1% HCl), and sample solutions are delivered by variable-speed multichannel peristaltic pumps. An electronically controlled switching valve alternates between blank and sample solutions, and two of the liquid streams (reductant and sample or reductant and blank) are butt-mixed in the sample valve, where the reaction starts to occur. The steams and all gaseous products are continuously and rapidly pumped into a glass gas–liquid separator, from which the gaseous products are carried, by argon gas, through a dryer system, finally reaching the AFS detector.

The design of the AFS detector for mercury analysis is relatively simple owing to the absence of a thermally energized atomizer.\(^ {55,57}\) Generally, a UV mercury vapor lamp is used as excitation source and the fluorescence light is detected by a PMT, which is positioned perpendicular to the excitation source. Figure 5 is a schematic diagram illustrating the optical configuration of an AFS system.\(^ {27}\) A glass chimney is used for introduction of mercury vapor into the optical path. The chimney is shielded with a high flow rate of argon. A 253.7-nm interference filter is employed between the introduction chimney and the PMT to keep stray light away from the latter.

![Figure 4 Schematic diagram of the continuous-flow vaporhydride generator. (Reproduced from PSA 10.055 Millennium Excalibur, User Manual, Issue 1.0, March 1998, by permission of P. S. Analytical.)](image-url)
### 3.1.1.2 Liberation and Reduction of Mercury

Since this system is used to determine total inorganic mercury (Hg\(^{2+}\)), the first requirement for performing analysis is to liberate all mercury compounds from the sample matrices and convert all organic forms of mercury to Hg\(^{2+}\) by various digestion/oxidation procedures.

For natural water sample analysis, the previously employed hot oxidizing method using permanganate–peroxodisulfate has been found unsuitable for low-level mercury determination because of the high blanks found in these reagents.\(^{58}\) Bromine monochloride has been found to be an excellent oxidant and preservative for total mercury in water samples,\(^{59}\) working faster and more efficiently on many organomercurials.\(^{58,59}\) Hydroxylamine hydrochloride is added to destroy the excess bromine before analysis with CVAFS. This method has often been used for converting organic mercury to Hg\(^{2+}\).\(^{58,59–64}\)

Both open-vessel and closed-vessel digestion/oxidation techniques have been described for solid sample (soil, sediment, and tissue) analysis.\(^{59,65–67}\) Open-vessel digestion results in considerable loss of organic mercury compounds by volatilization at elevated temperature or by incomplete oxidation of the sample matrix at ambient temperature. The open-vessel method is also complex and requires large amounts of glassware. These drawbacks can be overcome by using a closed decomposition system at elevated temperature. Microwave-assisted\(^{65,66}\) and autoclave-assisted\(^{67}\) closed-vessel digestion methods have been reported to achieve complete oxidation while minimizing losses of mercury. By using these closed-vessel methods, the preparation of the sample is effective and allows for a large number of samples to be prepared simultaneously and efficiently.

Once all forms of mercury have been converted to Hg\(^{2+}\), the latter is reduced to elemental mercury (Hg\(^0\)) by using either acidified stannous chloride or sodium borohydride (Equations 6 and 7):

\[
\begin{align*}
\text{Hg}^{2+} + \text{Sn}^{2+} & \longrightarrow \text{Hg}^0 + \text{Sn}^{4+} \\
\text{Hg}^{2+} + 2\text{NaBH}_4 + 6\text{H}_2\text{O} & \longrightarrow \text{Hg}^0 + 7\text{H}_2 + 2\text{H}_3\text{BO}_3 + 2\text{Na}^+
\end{align*}
\]

The mercury vapor produced is carried by argon gas to the AFS instrument for detection. A typical curve obtained using this type of CVAFS system is shown in Figure 6. Peak area is generally used for quantification. This system has been successfully applied to a wide range of environmental samples, such as water,\(^{56,60,63,66}\) soil,\(^{60,66,67}\) and biological samples.\(^{60,67}\)

### 3.1.1.3 Amalgamation

The concentrations of mercury in natural waters are often found to be at sub-parts per trillion (nanograms per liter) levels. The determination of such low concentrations frequently requires a preconcentration step prior to AFS detection. Many of the enrichment techniques are based on the fact that mercury can be deposited easily on metals such as gold and copper.\(^{58}\) The amalgam technique was used simply to improve the DLs of the cold-vapor technique. Normally, as shown in Figure 6, the mercury vapor is liberated slowly from solution and thus generates a broad signal. If instead the mercury vapor is collected by amalgamation,
on a gold trap, for example, and then subsequently released by heating the trap rapidly to 500–700 °C, a higher signal-to-noise ratio (S/N) is obtained. A two-stage gold trap technique coupled with AAS for determining total mercury in environmental samples was described.\(^\text{68}\) Gold-trap preconcentration of Hg\(^0\) followed by AFS has also been reported.\(^\text{57}\) Figure 7 shows a schematic diagram of the two-stage CVAFS system.\(^\text{69}\) Because of the excellent sensitivity provided by this technique, gold-trap CVAFS is currently widely used in environmental analysis.\(^\text{61,62,64,69–71}\) The United States Environmental Protection Agency (USEPA) has proposed, in the Federal Register, a method (Method 1631) for the determination of mercury in waters using oxidation, purge and trap, and CVAFS.\(^\text{73}\) However, trace levels of mercury have been found in most reagents used. The application of this technique is often limited by the fact that mercury present as impurity in these reagents is also preconcentrated.

3.1.1.4 Miscellaneous Atomic Fluorescence Spectrometric Techniques for Total Mercury Determination

LIF with ETA has been reported for total mercury determination with a 0.09-pg absolute DL. However, because of the small size of the sample to be used (only 10 µL), the concentration DL in water was only 9 ng L\(^{-1}\).\(^\text{72}\) This is not sufficient for total mercury determination in most natural waters, therefore limiting the application of this method.

Several flow-injection (FI) atomic fluorescence methods incorporating an on-line bromide–bromate oxidation step to determine mercury in water samples have been described.\(^\text{73,74}\) The CVAFS-based technique uses a heated reaction coil in the FI manifold to increase the conversion of organic mercury into Hg\(^{2+}\). However, the DL (6–25 ng L\(^{-1}\)) achieved by these techniques cannot, in many cases, meet the requirements for the analysis of environmental samples because only a small volume of sample can be used.

3.1.2 Mercury Speciation

Speciation is the identification and quantitation of the individual physicochemical forms of an element in a sample that together constitute its total concentration. It is well known that the various chemical forms (organic and inorganic) of mercury in the natural environment
behave differently, thereby affecting its biogeochemistry and toxicity to organisms. The development of analytical techniques able to distinguish different inorganic and organomercury species has been a main research area for scientists dealing with mercury in the environment. Basically, chromatography [gas chromatography (GC) and high-performance liquid chromatography (HPLC)]-based AFS, and purge and trap-based AFS are the two most widely used techniques for measuring inorganic and different forms of organomercury compounds, especially methylmercury.

3.1.2.1 Chromatographic Methods

Gas chromatography/electron capture detection (GC/ECD) was traditionally used for the determination of MeHgCl or MeHgBr. However, a major problem with GC/ECD is that the halogen-bearing compounds co-extracted with organic mercury interfere with the determination because of the nonspecificity of the ECD. Use of the very sensitive and selective AFS as a GC detector has successfully addressed this problem.

Gas chromatography/atomic fluorescence spectroscopy (GC/AFS) systems have been used for determination of methylmercury and ethylmercury in various environmental samples. A schematic diagram of the GC/AFS system is shown in Figure 8. A commercially available gas chromatograph, equipped with a megabore fused-silica column (DB-1 or BD-5), was used to separate organomercury chlorides or bromides. A pyrolyzer heated electrothermally at 800 °C was added between the column outlet and the AFS detector, converting organomercury compounds to Hg0. The pyrolyzer was made of deactivated fused-silica tubing. The mercury atoms formed in the pyrolysis unit were transferred via a 0.5-mm i.d. Teflon tube into the AFS detector, which has a similar design to that shown in Figure 5. Argon gas was used as make-up and shield gases, and both helium and argon could be used as the GC carrier gas. A typical chromatogram obtained using this system for the determination of methylmercury and ethylmercury compounds is given in Figure 9. Column maintenance is always an important step when a GC method is used for organomercury halide determination. With regard to the GC/AFS system, the treatment and maintenance of the GC injection port, the column, and sample preparation, have been discussed.

In order to improve GC performance, organomercury halides can also be converted to fully alkylated derivatives by different derivatization reactions before GC/AFS analysis. Two common derivatizing methods are ethylation using sodium tetraethylborate (NaBEt4) and alkylation with Grignard reagents (e.g. butylmagnesium chloride, BuMgCl). The application of NaBEt4 is limited because this procedure does not distinguish between ethylmercury and inorganic mercury (Hg2 ). The method of Grignard reactions has to be carried out in completely dried organic solvents and therefore involves tedious workup steps, which inevitably introduce analytical errors. Other derivatization reagents, such as sodium tetraphenylborate (NaBPh4) and sodium tetrapropylborate (NaBPr4), have also been studied and used for organomercury speciation by GC/AFS.

Sample preparation is one of the critical steps for MeHg determination in environmental samples. For water samples, liquid–liquid extraction (LLE) with an organic solvent has been a popular preconcentration method. However, the large volumes of both water sample and organic solvent required make it impractical for real sample analysis, especially when a large sample throughput is needed. The two currently used methods are based on steam distillation and solid-phase extraction with sulfhydryl cotton fiber. Isolation of organomercury compounds from soil and biological samples requires...
special attention because mercury species cannot be alternated during the isolation procedure. Recently, evaluation of some isolation methods for organomercury determination in soil and fish samples by GC/AFS has been reported.\(^{(79)}\)

### 3.1.2.2 Purge and Trap-based Gas Chromatographic/Cold-vapor Atomic Fluorescence Spectrometric Methods

Purge and trap methods for the determination of methylmercury requires conversion of ionic MeHg\(^+\) to nonionic species. The generally used method is aqueous ethylation with NaBEt\(_4\). The use of NaBEt\(_4\) as an aqueous derivatization agent was first reported by Rapsomanikis et al. for lead determination using an aqueous derivatization agent was first reported by Rapsomanikis et al. for lead determination using a purge and trap AAS system.\(^{(86)}\) Bloom reported an analytical method for determination of MeHg in aqueous samples by aqueous-phase ethylation with NaBEt\(_4\), followed by cryogenic gas chromatography/cold-vapor atomic fluorescence spectrometry (GC/CVAFS).\(^{(87)}\) Several studies and modifications have been conducted in terms of the trap materials and methods. In typical room-temperature trapping experiments, the volatile derivatives are trapped on a Carbotrap\(^\text{®}\) or Tenax-TA\(^\text{®}\) trap, thermally desorbed, separated by isothermal packed-column GC, decomposed at 700–900 °C by a pyrolyzer, and then detected by CVAFS.\(^{(88)}\) The cryogenic trapping method, the derivatives produced are purged by helium gas, trapped directly on a packed GC column immersed in liquid nitrogen (−196 °C), and then separated by electrothermally heating the column.\(^{(89)}\) The ethylation approach with room temperature trapping is at present the most popular method for speciation of mercury, but ethylation followed by cryogenic trapping is also effective.

Purge and trap CVAFS is an extremely sensitive method for mercury determination. A DL (3σ of the mean blank) of 0.016 ng L\(^{-1}\) for MeHg determination in water samples has been reported.\(^{(63)}\) However, this method cannot distinguish between inorganic mercury and ethylmercury because they both give diethylmercury as products. In addition, severe interferences are frequently encountered in the ethylation step and MeHg artifact has sometimes been observed when environmental samples with a high inorganic mercury content were analyzed.\(^{(90)}\)

Hydride-generation with NaBH\(_4\) for MeHg analysis was reported in 1992 by Filippelli et al.\(^{(91)}\) and Craig et al.\(^{(92)}\) MeHg was converted to volatile MeHgH, and Hg\(^{2+}\) was converted to Hg\(^0\) (Equations 8 and 9):

\[
\text{MeHg}^+ + \text{NaBH}_4 \rightarrow \text{MeHgH} \tag{8}
\]

\[
\text{Hg}^{2+} + \text{NaBH}_4 \rightarrow \text{Hg}^0 \tag{9}
\]

Several research groups have demonstrated the presence of MeHgH in the gas phase by using different techniques.\(^{(91, 92)}\) Hydride-generation followed by CVAFS was reported for mercury determination in various environmental samples.\(^{(93)}\)

### 3.1.2.3 Miscellaneous Atomic Fluorescence Spectrometric Techniques for Mercury Speciation

AFS can also be used as an HPLC detector. Hintelmann and Wilken described a method for the determination of organomercury compounds using HPLC with on-line AFS detection.\(^{(94)}\) The organomercury compounds separated by HPLC were converted to Hg\(^0\) in a continuous-flow system by an oxidizing, and a subsequent reducing solution. The Hg\(^0\) generated was separated in a gas–liquid separator and swept into the cell of an AFS detector by a stream of argon. This system was successfully used to separate eight organomercury compounds. The absolute limit of detection (LOD) for MeHg was reported to be about 0.02 ng. This corresponds to a concentration LOD of 0.8 µg L\(^{-1}\) for a 25-µL injected volume. Although HPLC has an advantage over GC in that formation of volatile derivatives is not necessary, the LOD achieved do not appear to meet the requirement for most environmental samples, especially for natural waters.

Recently, Cai et al. reported an analytical method involving ethylation using NaBEt\(_4\) followed by solid-phase microextraction (SPME) and GC/AFS detection for the rapid determination of methylmercury in fish.\(^{(81)}\) The procedure involves aqueous ethylation with NaBEt\(_4\) and adsorption of Et\(_2\)Hg and MeHgEt from aqueous solution or headspace on a fiber coated with poly(dimethylsiloxane). After retraction of the fiber into a syringe needle, the analytes are desorbed in an injection port of a gas chromatograph, separated, and detected by AFS using the system shown in Figure 8. At present this procedure cannot be used for the determination of MeHg in natural waters owing to the limited sensitivity.

### 3.2 Hydride-forming Elements

Many environmentally important elements, such as arsenic, selenium, bismuth, antimony, tellurium, germanium, tin, lead, and mercury, can form volatile and covalent hydrides with “nascent” hydrogen. Hydride-generation is a preferred technique when hydride-forming elements are to be analyzed by atomic spectrometry. The advantage of volatilization as a gaseous hydride clearly lies in the separation and enrichment of the analyte element and thus in a reduction or even complete elimination of interferences.\(^{(96)}\) Since many features of these hydride-generation techniques are similar between different elements in terms of the reactions and instrument designs, the analytical aspects of all these elements using
hydride-generation followed by AFS are discussed in this section. Of course, these elements can also be determined using other AFS techniques, which will be summarized in the next section along with the determination of other non-hydride-forming elements by AFS.

Since Holak in 1969 first applied hydride-generation for the determination of arsenic using AAS, \(^{95}\) a number of papers have been published describing modifications and optimization of the techniques. Currently, the number of metals and metalloids that can be determined by the hydride-generation technique has increased to about nine (arsenic, selenium, bismuth, antimony, tellurium, germanium, tin, lead, and mercury). Although the major research was carried out using AAS for detection, \(^{46}\) most of the elements have also been studied using hydride-generation followed by AFS detection. Tsuji and Kuga in 1974 \(^{96}\) were the first to describe hydride-generation coupled to nondispersive AFS. They reported a DL of 2 ng for arsenic analysis. Thompson in 1975 \(^{97}\) was the first to apply a dispersive AFS system for the determination of arsenic, selenium, antimony, and tellurium after hydride generation. DLs using this system ranged from 0.06 to 0.1 \(\mu\)g L\(^{-1}\).

Although various metal–acid reactions (e.g. Zn–HCl) have been used as a means of producing hydride, NaBH\(_4\) is currently used exclusively. By using NaBH\(_4\) as the reductant, the technique is easy to automate, since only solutions are involved, so that a high sample throughput can be achieved. In contrast to the manual injection of NaBH\(_4\) or sample solution into the reaction, all the solutions can be delivered by a continuous-flow hydride-generation system. \(^{12}\) Such a system is currently commercially available. \(^{14}\) The design of this system is similar to that of the cold-vapor generation system used in CVAFS for mercury analysis as shown in Figure 4.

Once the hydride has been formed and driven out of the solution, it can be directly delivered by an inert gas such as argon to the atomizer where it is excited by a fluorescence light source and measured by a detector such as solar blind PMT. The hydride produced can be first collected in a trap cooled in liquid nitrogen before it is warmed up to vaporize it for measurement. The configuration of this design is similar to that used in the purge and trap system for mercury determination discussed above. For routine analysis, the former (direct) method offers the advantage of a higher sample throughput and easy operation. However, the latter approach provides the highest yield and best sensitivity. \(^{46}\) Both procedures have been widely used in HG/AFS.

When determination is needed for different ionic species of elements present in a sample, various types of HPLC are employed to separate these forms of compounds, which are then subjected to hydride generation, followed by direct or purge and trap AFS detection. Sometimes an on-line decomposition step is added between HPLC and hydride generation to convert non-hydride-forming species into hydride-forming species. A chemical reagent, such as potassium peroxodisulfate, assisted by UV photochemical oxidation or microwave digestion has been used for this purpose. \(^{98–101}\)

Although occasionally an electrothermal atomizer has been used, an argon–hydrogen diffusion flame atomizer is the usual choice because of very low background radiation, easy decomposition of hydrides in such a low-temperature flame, and the low quenching effect in the argon-supported flame. The atomization mechanisms of hydrides in different atomizers have been studied extensively. Evidence has been presented showing that the atomization of hydrides in a cool argon–hydrogen diffusion flame is not the result of a simple thermal dissociation process. \(^{12,35,46}\) Dedina and Rubeška concluded that atomization is brought about by free radicals produced in the primary reaction zone of the oxygen/hydrogen flame according to Equations (10–12):

\[
\begin{align*}
H + O_2 &\rightarrow OH + O \quad (10) \\
O + H_2 &\rightarrow OH + H \quad (11) \\
OH + H_2 &\rightarrow H_2O + H \quad (12)
\end{align*}
\]

It can be shown that the concentration of H radicals is several orders of magnitude higher than that of OH radicals. Taking selenium as an example, the atomization is via a two-step mechanism with the predominating H radicals (Equations 13 and 14):

\[
\begin{align*}
SeH_2 + H &\rightarrow SeH + H_2 \quad (13) \\
SeH + H &\rightarrow Se + H_2 \quad (14)
\end{align*}
\]

It has already been shown that there is a large number of H radicals present in an argon–hydrogen diffusion flame, so the same reaction mechanisms can be expected. \(^{46}\)

As with any other technique, HG/AFS suffers from interferences. Welz \(^{46}\) gave an extensive discussion about various interferences encountered in hydride-generation methods. However, the sensitivity of the AFS system allows dilution of the sample so that the interferences are reduced significantly. Spectral interference is not a problem for HG/AFS because the analyte element passes into the atomizer as gaseous hydride, while concomitants normally remain in the reaction vessel. In most currently used nondispersive AFS detectors, an interference filter is located between the atomizer and the PMT, to reduce the flame background and emissions from the excitation source that do not produce intense fluorescence lines. \(^{12}\) The flame background can also be minimized by choosing suitable flow rates of gases. Kinetic interferences are
caused by varying rates of development or liberation of the hydride from solution. These interferences only occur in the direct hydride-generation system, and not in the purge and trap system. A typical kinetic interference is the retardation of hydride liberation because of the sample matrix effect. Chemical interferences are perhaps the most frequently encountered problem. It appears that transition metals interfere significantly with hydride-generation reactions.

### 3.2.1 Arsenic

Arsenic was the first element to be determined using the HG/AFS technique. A number of papers have been published on arsenic determination in environmental samples. Azad et al. described a procedure for the determination of arsenic in soil digests in which arsine was generated with NaBH₄, passed to an argon–hydrogen air-entrained flame and an atomic fluorescence signal, excited by a modulated EDL, and measured using nondispersive AFS. The authors reported a DL of 3 µg L⁻¹ calculated as the mass of arsenic required to produce a S/N of 2 for the atomic fluorescence signal. Most papers published in the past utilized an EDL as the excitation source because this type of lamp provides intense and narrow lines. However, the EDL is often unpredictable in use and requires careful temperature control to achieve good stability. A BDHCL seems to be a reliable high-intensity excitation source and this type of lamp has been used in commercial AFS instruments. Corns et al. described a fully automated continuous-flow hydrogen generation AFS system for the determination of hydride-forming elements, principally arsenic and selenium. A miniature argon–hydrogen diffusion flame was used as the atomizer and a BDHCL was used as the excitation sources. The hydrogen for the flame was chemically generated as a byproduct of the NaBH₄ reduction. Fluorescence wavelengths of interest were selected using an interference filter. A solar blind PMT was used as the detector. A DL (3σ) of 0.1 µg L⁻¹ was reported for arsenic.

To date, about a dozen arsenic compounds have been found in environmental samples. Extensive studies on the toxicity and biogeochemistry of arsenic have clearly depicted the importance of the chemical speciation of this element. To determine these different forms of arsenic in environmental samples, a powerful separation technique, such as HPLC, has to be used. A number of analytical systems based on high-performance liquid chromatography/hydride-generation/atomic fluorescence spectrometry (HPLC/HG/AFS) have been reported. Recently, Gomez-Ariza et al. described an anion-exchange HPLC/HG/AFS system for the speciation of arsenite, arsenate, dimethylarsinic acid (DMAA), and monomethylarsonic acid (MMAA). The products of hydride-generation of arsenite, arsenate, DMAA, and MMAA are arsine (AsH₃), arsine, Me₂AsH, and MeAsH₂, respectively. DLs of 0.17, 0.38, 0.45 and 0.30 µg L⁻¹ were reported for arsenite, arsenate, DMAA, and MMAA, respectively. A schematic diagram of this system is shown in Figure 10. Arsenobetaine, a non-hydride-forming species of arsenic, was also determined by introducing an on-line photooxidation step after the chromatographic separation. Le et al. described an on-line microwave derivatization coupled with HPLC/HG/AFS for arsenic speciation. They studied the separation of 11 arsenic compounds by using ion-pair chromatography at 30, 50, and 70 °C column temperature and found that the use of elevated column temperature improved the separation efficiency and dramatically reduced the chromatographic time for some arsenic species. This speciation technique was successfully applied to a study of metabolites of arseno sugars present in commercial seaweed products. A typical chromatogram obtained for speciation of seven arsenic compounds is shown in Figure 11.

Hydride-generation followed by purge and trap AFS can also be used for speciation of hydride-forming arsenic compounds. A schematic diagram of this system is shown in Figure 10.

species such as arsenite, arsenate, DMAA, and MMAA. A pH-selective hydride-generation process should be used. This process comprises two steps. First, arsenite is reduced to AsH₃ by NaBH₄ at pH 6. The product is swept out of the solution and collected with a cooled trap under liquid nitrogen. The trap is then allowed to warm to room temperature and the arsine is released into the AFS system for detection. Second, arsenate, DMAA, and MMAA in the sample solution are reduced to the corresponding arsines at pH 1, then followed by purge and trap AFS detection.

3.2.2 Selenium

The AFS determination of selenium was first reported by Dagnall et al. using a dispersive spectrometer equipped with an air–propane flame giving a DL of 0.25 μg mL⁻¹ of selenium on aspiration of aqueous solution using a pneumatic nebulizer. A dramatic improvement in DL (10 μg L⁻¹) was obtained by using a similar experimental arrangement, but using an argon–hydrogen diffusion flame and the hydride-generation technique. This HG/AFS system was used for the determination of selenium in soil samples. A current commercially available HG/AFS instrument utilizes a BDHCL as the excitation source and also an argon–hydrogen diffusion flame as the atomizer. A DL (3σ) of 0.05 μg L⁻¹ was reported. A standard reference material (SRM) for trace elements in water, SRM 1643d from the National Institute of Standards and Technology (NIST) (Gaithersburg, MD, USA), was used to test the performance of this system. The concentration of selenium was found to be 11.40 ± 0.07 μg L⁻¹ (n = 3), which was in close agreement with the certified value of 11.43 ± 0.17 μg L⁻¹.

Selenium can also exist as different forms, both inorganic and organic, in environmental samples. Volatile organic selenium compounds can be directly determined using purge and trap followed by AFS without derivatization (see the next section). The determination of inorganic forms, Se(IV) and Se(VI), at low concentration levels is generally carried out using the hydride-generation technique. Since only Se(IV) is able to generate the hydride, if speciation data are required two procedures are usually used. In the first procedure, the sample has first to be analyzed without pretreatment, which provides the Se(IV) concentration. Then the sample is treated by heating it with 6 mol L⁻¹ hydrochloric acid, which reduces any Se(VI) to Se(IV). The analysis is performed again, to give a total concentration of inorganic selenium present in the sample. The concentration of Se(VI) is then calculated by difference. The obvious disadvantage of this method is its indirect determination of Se(VI), which involves the errors induced by determination of Se(IV) and total inorganic selenium. The speciation of Se(IV) and Se(VI) can also be carried out using HPLC separation followed by detection with different detectors. Pitts et al. recently described an on-line method for determination of inorganic selenium species in aqueous samples using HPLC/HG/AFS. Separation of these species was achieved using HPLC, after which the analyte was acidified, and passed through an on-line microwave system. The latter stage left the Se(IV) unaltered, but transformed Se(VI) to Se(IV). The selenium hydride was then determined using an AFS detector. DLs of 0.2 and 0.3 μg L⁻¹ were reported for Se(IV) and Se(VI), respectively.

3.2.3 Other Hydride-forming Elements

In addition to arsenic and selenium, other elements such as antimony, bismuth, tellurium, germanium, tin, and lead have also been determined using HG/AFS. It should be noted that the arrangements of the instruments used for the analysis of these elements are identical with those for arsenic and selenium except for the utilization of a corresponding excitation source and wavelength-selection system. Both dispersive and nondispersive AFS have been used. Kobayashi et al. published the first paper on the determination of bismuth using an HG/AFS system. They used an argon–hydrogen diffusion flame as the atomizer and a microwave-excited EDL as the excitation source, and achieved a DL of 5 μg L⁻¹ or 0.1 ng of bismuth. Nakahara et al.
described an analytical method based on HG/AFS for the determination of tellurium using an argon–hydrogen diffusion flame and an EDL excitation source. The comparison of the Zn and NaBH₄ reduction methods was discussed. The best attainable DLs for tellurium were 0.1 µg L⁻¹ (2 ng) and 1.5 µg L⁻¹ (30 ng).

Nakahara et al. have also conducted a series of studies on the determination of other hydride-forming elements using hydride generation coupled with nondispersive AFS. D’Ulivo and Papoff described a method using nondispersive AFS combined with hydride generation for the determination of lead. They used a radio-frequency-excited EDL as the excitation source and a small argon–hydrogen flame as the atomizer. The DL was 0.06 µg L⁻¹ and the calibration curve was linear up to 300 µg L⁻¹, superior to HG/AAS or inductively coupled plasma atomic emission spectrometry (ICP/AES).

Using a similar HG/AFS system, D’Ulivo et al. determined dialkyllead and trialkyllead. The DLs obtained for trimethyl, triethyl, dimethyl, and diethyllead (3σ) were 3–5 ng L⁻¹. Although HG/AFS is an appropriate analytical technique for the determination of these hydride-forming elements, its application in environmental analysis seems to be very limited. This is due, in part, to the fact that until recently no commercial HG/AFS instruments were available. Most of the research was carried out using laboratory-made systems. However, a continuous-flow HG/AFS system, recently made commercially available, provides a capability for arsenic, selenium, antimony, tellurium, and bismuth determination with a DL in the sub-parts per billion region.

### 3.3 Non-hydride-generation Methods

#### 3.3.1 Laser-induced Fluorescence

Determinations of hydride-forming elements in environmental samples are usually carried out using HG/AFS because of its high sensitivity and simplicity. Another very sensitive type of AFS, which has been used for the determination of many elements (both hydride-forming and non-hydride-forming), is LIF. LIF provides the lowest absolute DLs for a number of elements.

Although different types of atomizers, such as flame, plasma, and electrothermal, can be coupled with LIF, it appears that the most sensitive practical measurements by LIF are performed in those ETA instruments, such as graphite-tube furnaces, that are currently used in AAS. With an ETA as atomizer, absolute DLs below femtogram level can be obtained experimentally for some elements. Omenetto collected pertinent data for 22 elements investigated with LIF/ETA and the DLs were compared with those given by inductively coupled plasma mass spectrometry (ICP/MS). For most elements, the data obtained using LIF/ETA are superior to those obtained using ICP/MS. Recently, a DL of 10 fg mL⁻¹ (100 ag absolute) was reported for lead determination in whole-blood samples using LIF/ETA.

A schematic diagram of the experimental design for LIF/ETA is shown in Figure 12.
LIF/ETA has been used for the determination of a number of elements in various environmental samples. Bolshov et al.\(^{24}\) reported the results for the determination of cadmium in Antarctic and Greenland snow and ice by LIF/ETA. The DL was found to be 0.5 fg or 0.01 pg g\(^{-1}\) using a 50-µL sample volume. Silver was determined in seawater by LIF using novel diffusive graphite-tube ETA.\(^{113}\) A 10-µL volume of sample was applied to a small graphite boat attached to one of the graphite electrodes and inserted into the graphite tube, which was then sealed by the electrodes and heated. The vaporized silver passed through the graphite wall and was excited by a laser beam a few millimeters above the surface of the tube. A DL of 90 fg for 1 : 1 diluted seawater was obtained. Other examples of recent applications of LIF/ETA include the determination of aluminum and lead\(^{114}\) in atmospheric aerosol samples, antimony\(^{40}\) in biological and environmental samples, bismuth\(^{115}\) cobalt,\(^{116}\) and lead\(^{25}\) in seawater, thallium\(^{117}\) and lead\(^{118}\) in natural water, and mercury\(^{119}\) in soil.

LIF coupled with flame atomization has also been used for environmental sample analysis. Zhou et al.\(^{21}\) described methods for the determination of cobalt, copper, lead, manganese, and thallium in Buffalo River sediment using flame LIF. A standard, long-path flame atomic absorption burner was used and DLs for cobalt (2 ng mL\(^{-1}\)), copper (2 ng mL\(^{-1}\)), lead (0.4 ng mL\(^{-1}\)), and thallium (0.9 ng mL\(^{-1}\)) were reported.

One of the major problems facing the future use of LIF instruments is that lasers are difficult to use. They are costly and require highly skilled operators. This certainly limits the development of commercially available instruments.

### 3.3.2 Atomic Fluorescence Spectrometry as a Chromatographic Detection Method

AFS can be conveniently used as a detection method for chromatography, such as GC and HPLC. Details can be found in an excellent paper by D’Ulivo.\(^7\) who summarized the research regarding the utilization of AFS in chromatographic detection. Brief information is given below.

Van Loon et al.\(^{120}\) first described a method for the simultaneous speciation of several elements using an atomic fluorescence spectrometer as an element-specific detector for chromatography. A three-channel nondispersive atomic fluorescence spectrometer with an HCL as the excitation source and a nitrogen-sheathed air–acetylene flame as the atomizer was used. It was interfaced to an HPLC system by direct connection of the column outflow to the nebulizer capillary of the burner. The column flow rate was compatible with the nebulizer flow rate. The technique was successfully applied to the simultaneous detection of several metals as their EDTA (copper, zinc, nickel), glycine (copper, zinc, nickel), and trien complexes. More research has been carried out to study metal speciation using different models of coupling of HPLC with AFS.\(^{121}\)

Coupling AFS to GC greatly simplifies the task of the atomizer since the effluents supplied to the AFS system are already in the vapor phase.\(^7\) Different types of atomizers have been designed and applied to the speciation of metals.\(^{122}\) D’Ulivo and Papoff\(^{123}\) described a technique using GC coupled with multichannel nondispersive AFS for the simultaneous determination of alkyl-lead, alkyltin, and alkylselenide compounds. Recently, Pécheurian et al.\(^{124}\) described a GC/AFS method for the determination of ultratrace volatile selenium species in aqueous solutions. The method, optimized for field measurements of volatile selenium species in aquatic environments, involved a shipboard purge of the water samples collected under clean conditions, a cryogenic trapping stage followed by separation of the analytes by low-temperature chromatography. Under routine operating conditions, absolute DLs of 4 and 4.5 pg of Se for Me\(_2\)Se and Me\(_2\)Se\(_2\) were obtained, respectively.

It is expected that recent developments will strengthen the role of commercial AFS in the determination of trace elements in environmental samples. Indeed, AFS has already been shown to be the most sensitive and important detection technique for mercury determination, especially for samples with low concentration levels.

### 4 CONCLUSIONS

Clearly, the most important and widely used AFS systems in environmental analysis have so far been CVAFS for mercury and HG/AFS for the determination of the hydride-forming elements. In practical terms, for environmental and other areas of analysis, the broader adoption of AFS will depend on the introduction of standardized commercial instrumentation and the ability to compete with other techniques that are commonly used, such as AAS, AES, and ICP/MS. Currently, several companies manufacture AFS detectors used either for mercury or hydride-forming elements, or both. These AFS detectors are of simple design and easy operation. Most importantly, these cost-effective instruments provide excellent DLs for some environmentally important elements, such as mercury. Important progress is, therefore, expected in using these instruments for environmental analysis.

Although LIF has practical limitations at present, such as high cost and difficult operation, the exceptional low DLs achieved using LIF for some elements are very attractive. This is especially true when only small sample amounts are available.
ACKNOWLEDGMENTS

It is a pleasure to acknowledge the encouragement given to me during preparation of this article by Dr Rudolf Jaffé. Special thanks are due to Anita Holloway for her assistance in the preparation of the manuscript. I wish to express my thanks to the many authors and publishers who have given permission for the reproduction of figures from the original literature. This is SERP contribution number 106.

The most difficult samples to analyze are those derived from biological sources. The analysis of biological samples requires the ability to extract and isolate a wide range of environmental pollutants from an even wider range of matrices, from simple bacteria to tissues and fluids from humans, from fungi to the complex tissues and structures of the plants and products that compose the food chain. These matrices comprise a variety of cells, connective tissues and fibers, fluids and related materials that introduce literally thousands of different organic and inorganic compounds to every analysis effort. In order to recognize and assess the nature and severity of pollution and its impact on humans as well as the flora and fauna that constitute our environment, highly efficient and selective methods for the extraction and cleanup of such samples must be developed. New developments in analytical science have been brought to bear on this problem, speeding the extraction and analysis process while making the resulting analyses more sensitive and selective. The present article examines the historical approach to the extraction and cleanup of biological samples for the analysis of pollutants, and reviews recent advances in technology and methodology that have proven applicable to this field.
been developed by chemists already in the area, applied in an effort to solve the many difficult analytical tasks with which they were, and continue to be, presented in performing environmental analyses in biological samples. Many of the problems faced in this and other areas of the analytical sciences are the same, however, and involve the need to perform adequate sample preparation, homogenization and disruption, sample/target analyte(s) isolation, analyte(s) resolution from co-extracted sample components and analyte(s) detection and quantitation.

To begin to analyze a biological sample for a compound of environmental interest, certain steps must be taken to assure the quality and reliability of the result. The value of this analytical result is directly related to the procedures used for sample preparation. Sample preparation is not merely the steps required in the homogenization, extraction and cleanup prior to introduction to an instrument. It also requires consideration of the level of documentation, appropriate procedures for sample collection, storage and shipment, assuring the stability of the sample and the target analytes and the processing of the sample necessary before extraction begins.

The methods applied for these processes require the development and thorough validation of the procedures to be employed. As well as this being simply good laboratory practice (GLP), it must also be noted that the results from environmental analyses are often used in litigation and may prove essential to making decisions concerning threats to the public health. Thus, regulatory authorities at many levels of government have established, through law and regulation, analytical procedures and methods that have been proven to be highly reliable. These “official methods” have withstood the test of time, as well as the courts, but have been modified over the years to incorporate new technologies and approaches. Such modifications must, however, prove to be equivalent to or better than the techniques they replace.

The trend in sample preparation and cleanup is away from the use of procedures that require large volumes of extracting solvent, large sample size and complicated and expensive glassware and/or instrumentation that have characterized “classical” methods for environmental analysis. Such methods are being replaced by techniques that require smaller sample sizes, offer generic extraction techniques and that can be readily automated to speed obtaining the results of an analysis. The field is further evolving to include the use of immunoassay, affinity chromatography, biosensing and other analytical advances to even further simplify or completely eliminate the processes previously required for sample preparation and cleanup. Such advances are being assisted by the new generation of analytical instruments that provide greater sensitivity, selectivity and speed of analysis.

The present article will address the general processes and principles involved in the preparation and cleanup of biological samples prior to analysis for environmentally relevant pollutants. It will address these issues from a historical perspective, examining “official” methods for the analysis of pollutants and discussing newer techniques that are slowly replacing more classical approaches. It is noted here that it is not possible to cover every biological matrix or environmental pollutant of interest and that each combination of target analyte and sample can present unique complications. Indeed, the analysis of thousands of environmental pollutants, ranging from alar on apples to PCBs in the hepatopancreas of crayfish, and the variety of biota, encompassing all five kingdoms that are exposed to them, constitute a major challenge to the analytical chemist. The methods developed to isolate, detect, identify and quantify these compounds are, however, essential to maintaining the health of the food supply and our environment and provide us with the capacity to identify, regulate and correct environmental hazards.

Much of the information, references and examples presented will be based on analyses conducted in aquatic species for environmental pollutants such as chlorinated pesticides, herbicides, PAHs and PCBs. Attention to single compounds and specialized protocols will not be addressed here. Nevertheless, the principles involved do address both the problems and the solutions to be encountered in dealing with biological samples in general in environmental analyses.

1.1 The Exposure of Flora and Fauna to Pollutants

Pollution is a relative term. Natural processes, such as forest fires, thermal venting, leaching of metals and minerals by groundwater and rain, and photochemical reactions in the atmosphere, are all processes that can contribute to alteration of the natural chemical state of a given ecosystem. This alteration of the environment can be seen as a pollution of the native molecular scheme. Changes in this chemical scheme can be measured relative to its initial state or relative to other areas to assess the degree of change.

The evolution of human technologies and the ever-increasing population of the planet have, however, added significantly to these natural processes. Humankind has also introduced many molecular species never before seen in the natural environment.

The use of fossil fuels, the industrialization of many nations’ economies, the industrialization of agriculture, our struggles to handle our manufacturing and human wastes have spiraled as we have sought a higher standard of living through increased production. These efforts for our well-being have often been at the expense of the flora and fauna whose ancestors readily predated our own on
this planet. It has also been at our own peril. It has become a vicious cycle of the interactions of the environment's natural processes with humankind's introduction of unnatural substances, polluting and contaminating the cycle of life.

It is perhaps ironic that the justification for the original production and use of many herbicides, pesticides and other manufactured pollutants, such as their environmental or thermal stability, intended toxicity toward a particular pest, etc., eventually led to their becoming a continuing threat to the environment. For example, while the chlorinated pesticides were valuable for crop and animal agriculture, they also persisted in the environment, being highly stable to most aspects of environmental degradation. From the producers' point of view this was advantageous, reducing the frequency of application of the pesticide and the costs inherent in the process. However, as the toxicity of many of these compounds became evident, this persistence became the very cause for the removal of many such products from the market in the USA. Unfortunately, large quantities of many of these compounds, as well as others, have continued to be used in developing countries around the world.

Of further concern has been the level of these compounds that has accumulated in the environment from spraying, from legal and illegal dumping, and from sequestration in soils and sediments from which continuing diffusion of these materials into various habitats and resources can occur. Since many of these compounds are highly lipophilic, they tend to accumulate in fatty as well as other tissues of animals that compose the food chain. For aquatic environments, even coastal and deep-sea species have been found to contain detectable levels of many such compounds on a decreasing concentration gradient as one moves farther from land and away from river-influenced bays, gulfs and ocean currents.

The persistence of many classes of pollutants, their magnification through bioaccumulation and the concerns for their known and unknown toxicity require that state, federal and international monitoring programs provide mechanisms for assessment and remediation. However, state, national and international programs have not always proven to be capable of being integrated. This is in part due to the variety of biological matrices that one encounters when dealing with analyses of pollutants. It has also led to a degree of confusion in the field and has underscored the need for new methodology that can rapidly assess a pollution problem. This demand is further heightened by the fact that adequate monitoring will require the analysis of more samples for more compounds in shorter time frames than existing methods can currently handle.

The role of the analytical chemist in this situation is to provide methodology to identify and measure the compounds that we define as pollutants. Identification and measurement are the first steps in recognition and amelioration of the problem.

1.2 Biological Sentinels for Monitoring Pollution

We can readily acknowledge the exposure of the environment to contaminants. We may then also note that these environments are filled with native plants and animals, which have unwittingly offered themselves as sentinels to their own, and to our, exposure. Thus, the practice of analyzing biological matrices from the field for environmental contaminants has been used extensively as a general environmental monitoring strategy, accompanied by measurements in soils, sediments, water and air. We have extended this strategy by actually placing particular species in an area to further allow assessment of exposure under more controlled conditions. The use of such an approach, taking advantage of the ability of plants and animals to bioconcentrate pollutants, is defensible in the sense that we are most concerned about the impact of pollution on living beings and, most selfishly, ourselves. Furthermore, such efforts may be justified based on the fact that the levels of environmental contaminants in water are often too low to detect or quantify by conventional analytical methods, requiring significant efforts at concentrating residues. The effort to measure contaminants in water can be further complicated if the contamination originates from a point source into a moving stream or river. As a result, the use of biomonitors or environmental sentinels has been proposed as a method to determine the status of contamination by chemicals at both the tissue residue and the genetic level. This idea takes advantage of the bioaccumulating ability of some organisms for lipophilic organic chemicals, which is the category into which many of the environmental pollutants fall. For example, mussels (Mytilus species, for example) have been used in the past in the United States Environmental Protection Agency (USEPA) “Mussel Watch” program as convenient, sedentary sentinels. The high lipid content and water-filtering function and capacity of both mussels and oysters make them ideal monitors of aquatic pollution. They may also be placed in baskets or pens to protect them from predators and strategically located in a grid pattern to obtain more controlled data.

Investigations have also used other species to monitor environmental contamination in water. Catfish (Ictalurus punctatus, for example) are also a logical model species to investigate new analytical sample preparation techniques since they are filter feeders, bottom dwellers and an important food source. Thus, any sedentary or relatively stationary species may serve as a living record of past exposure. Taken in combination with other data from soils, sediments, water, etc., this can provide an
1.3 Analytical Chemistry’s Role in Responding to Environmental Pollution

How do we determine when a system has become polluted? How do we define the source and the nature of the pollutants involved? The ability to detect and assess the impacts of toxic wastes on various environments and the species that populate them is dependent on the ability to perform analyses of the water, sediments, soils and tissues of the affected biota. Such analyses must encompass the attributes of high efficiency of isolation, adequate sensitivity, specificity and linearity of response to whatever system of detection and identification is employed. Such methods must be of high quality, accurate, precise and reproducible, supplemented by a high degree of documentation, quality assurance (QA) and quality control (QC). Such methods must be thoroughly documented and validated as being able to be conducted in a number of different laboratories. In the USA this undertaking has been assumed by the government. In association with professional organizations, private industry and universities, there has been success in bringing some order to the chaos. This does not imply perfection, however.

While there has been significant progress in the recent past in the ability to extract and analyze pollutants in water, mainly due to solid-phase extraction (SPE)-disc technologies and advances in instrumentation ease of use and sensitivity, there has yet to be such dramatic progress in performing analyses in biological samples. The preparation and cleanup of such samples for submission to advanced analysis by our evolving instrumentation has remained a difficult and cumbersome task.

Most methods recommended by various governments for dealing with biological samples involve the classical approach of sample disruption, solvent/solvent extractions, back-extractions and column chromatographic cleanup steps. Analytical chemists have long recognized that such methods are limited in their turnaround or response times and expend large volumes of solvent and personnel hours, especially when they must be applied to large numbers of samples. The solvent use is of particular concern since many of the methods require the use of liters of solvent even for a single sample, solvent that is often evaporated into the atmosphere, polluting thousands of liters of air. Discarded solvent must be handled as hazardous waste, adding large volumes of solvent residues to already burdened disposal sites and greatly adding to the overall costs of solvent disposal, not to mention the initial costs of solvent purchase and the unknown costs of personnel exposure. Many of these methods may, in the final analysis, contribute more pollution to the environment than they ever detect. For these reasons future directions for the analyses of toxic wastes and pollutants in general will proceed through the development of simple, generic and environmentally friendly methods that require little or no solvent and that are capable of providing data in rapid response to inquiries concerning contamination and waste remediation.

2 ENVIRONMENTAL REGULATIONS AND METHODS: THE RESPONSE OF GOVERNMENTS TO THE PROBLEMS OF POLLUTION

The final expression of frustration in dealing with any serious problem is the establishment of a governmental agency to study and attempt to control the problem. Laws are passed and regulations are written. Once the regulations and laws are put into practice, bureaucrats are imbued with the authority to interpret them and to write further regulations to regulate the regulations already in place. Then come the judiciary to settle the disputes between the regulators and the regulated. On an international basis the situation can become even more complicated as the laws of one nation clash with those of its neighbor. However, pollution is at once local, national and international, with all nations sharing the same air, the same water and the same global environment in the end.

2.1 The Development of Laws, Regulations and Regulatory Agencies for Monitoring Environmental Pollution

A number of legislative events enacted in the USA since the late 1960s have initiated the development and standardization of analytical methods for environmental contaminants in general. An overview of early environmental legislation has been presented by Foster. The first modern major legislative act approved in 1969 by the United States Congress was the National Environmental Policy Act (NEPA) and the Environmental Quality Improvement Act (EQIA) of 1970. Shortly thereafter,
Congress created the USEPA from which to coordinate government action and focus authority for protecting the environment. As a result, the USEPA implemented four major pieces of environmental legislation. Amendments to the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947 and the Federal Water Pollution Control Act (FWPCA) of 1948, in 1972 placed them under the control of the USEPA. Another piece of legislation in 1972 was the enactment of the Marine Protection Research and Sanctuaries Act (MPRSA) implemented to expand the United States protection of the open ocean to the extent of their authority. In 1976, the Toxic Substances Control Act (TSCA) gave the USEPA regulatory control over commercial chemical use. Other significant enactments of environmental legislation since then have been Resource Conservation and Recovery Act (RCRA) and Superfund.

Ultimately, three federal agencies participate in the responsibilities of regulating pesticides and related compounds for the United States. The USEPA (see above), the United States Department of Agriculture (USDA), and the Food and Drug Administration (FDA). The USEPA has the responsibility of approving the use of pesticides as well as establishing residue tolerances in foods.\(^7\) The USDA enforces these tolerances in meat and poultry and the FDA is in charge of enforcing residue tolerances for any other food products shipped in interstate commerce\(^8\) although the FDA does play a role in aiding the USEPA in establishing residue goals.\(^9\)

Currently, the FDA conducts an extensive residue monitoring program each year involving the analysis of over 20,000 samples using multiple residue methods. An overview of this program and the results since 1978 has been described.\(^10–14\) Data collection and dissemination programs have been implemented by the FDA.\(^15,16\) Seafood and seafood products, although not required to pass unified, continual federal inspections by the FDA, remain a concern with the public because of the specter of environmental contaminants\(^17\) occurring in the open ocean and off the coasts of other nations as well as the USA. In 1965, the United States Bureau of Commercial Fisheries began the National Pesticide Monitoring Program, which lasted until 1972, to monitor chlorinated pesticide residues in shellfish populations off the coast of 15 states.\(^18\) The results demonstrated that 1,1,1-trichloro-2,2-bis[p-chlorophenyl]ethane (DDT) (CAS 50-29-3) was virtually ubiquitous. This program was continued to 1976 and indicated that pesticide concentrations were declining.\(^19\) In 1977, the USEPA conducted a one-time sampling event of bivalves from the estuaries previously monitored under the National Pesticide Monitoring Program which demonstrated that the presence of pesticides had continued to decline dramatically.\(^20\)

The Food Safety and Inspection Service (FSIS) of the USDA is responsible for monitoring the residues of chemicals that might be present in meat and poultry products. This responsibility is manifested into the National Residue Program (NRP). The NRP enables the sampling and testing of meat and meat products for residues from pesticides, environmental contaminants and animal drugs.\(^21,22\)

The National Oceanic and Atmospheric Administration (NOAA) created the National Status and Trends (NS&T) Program to assess the effects of human activity on the quality of coastal and estuarine habitats throughout the USA. This program was designed to monitor chemical contamination and the biological effects of chemical contamination. Two efforts were begun in 1984 and 1986 to monitor the tissues of benthic fish (The Benthic Surveillance Program) and bivalve molluscs and sediments (The Mussel Watch Program), respectively. Results and some of the early trends from these programs have been reviewed.\(^23,24\)

A problem arising from the existence of so many monitoring and data gathering programs is the lack of integration of the enormous amount of information that is generated. As a result, policy and decision makers seldom have easy access to this information from which to prioritize research or determine to what extent policy goals are being attained. From this concern, the USEPA has initiated an integrated program for monitoring ecological status and trends known as the Environmental Monitoring and Assessment Program (EMAP).\(^25\) The problem of integrating various sources of environmental monitoring and residue data are even greater when one considers this issue globally.

Outside the USA, there are over 50 international organizations that are involved with pesticides and other pollutants. However, there are legitimate concerns pertaining to the ability of developing nations to possess the resources necessary to evaluate toxicity from contaminated food or perform residue monitoring. As a result, the United Nations has several organizations to address the problems of conflicting agencies and countries with limited resources. A review of these efforts and the problems that exist has been published.\(^26\)

Even with the existence of substantial legislation and monitoring programs enacted to protect the consumer from harmful chemical residues in food, the public remains concerned over the issue. According to a review\(^27\) on dietary pesticide risk assessment, 80% of shoppers surveyed in USA stated that pesticide residues in foods were a major concern. The subject of pesticides and food safety has been reviewed\(^28\) as have residue concerns in seafoods.\(^29–31\)
2.2 Early Analytical Efforts to Respond to Pollution Events

With the introduction of the chlorinated pesticides after the second World War and the general boom in industrial manufacturing and chemical synthesis, pollution of the environment proceeded almost unabated. It was not long before the toxicity of the by-products, wastes and the products themselves to the environment became evident. When the need to analyze for these materials was realized, the technology of the time was the first to be applied to their isolation and analysis. Most of this 1940s and 1950s analytical approach is still in use today. The same can be said of almost all recognized classical and/or official pollutant methods.

Most “classical” methods were based on homogenization of the sample matrix with an extracting solvent followed by extensive cleanup procedures to remove, for the most part, lipids and other co-extracting neutral compounds. Water and aqueous homogenate samples were extracted by liquid–liquid partitioning of the pesticides followed by a range of extraction protocols to remove interferences or clean up the sample from emulsions, tissue debris, etc.

Early determinative analyses were often conducted by non-chromatographic methods using measurement of total chlorine content, ultraviolet (UV), visible, and fluorescence spectroscopy. Biochemical techniques that took advantage of the activity of the compound on specific enzyme systems or organisms, such as acetylcholinesterase activity and the survival time of flies exposed to the extracts for certain pesticides were also used.  

Such methodologies were most often developed for single compounds. However, as a large number of such compounds became available, the extraction methodology had to become more nonspecific while the analytical methodology had to become more specific. The development of multiresidue methods became a necessity and was fostered by the growing need and concern to monitor for residues in agricultural crops and food animals that were exposed to such compounds. This led to the development of a variety of techniques that were based on different aspects of the nature of the pollutants and the sample matrix to be tested. Many of these procedures, particularly the “Mills’ method” for chlorinated pesticides, were subsequently incorporated into what are now “official” methods of analysis for these compounds. Nevertheless, these methods have been regularly revised and still adhere to rather antiquated processes for sample homogenization, extraction and cleanup that are labor-, materials- and solvent-intensive. Furthermore, most of these methods have not been adequately examined for method performance in the variety of food-animal species and agricultural products available and must be validated anew for each application.

It became evident that the burgeoning publications of new methods and approaches would have to be centrally controlled and assessed and that particular government agencies should be appointed to control and regulate both the use of the methods and the use and production of these chemicals as potential pollutants. Enter the politicians and the accompanying bureaucrats.

2.3 The Evolution of Analytical Methods into Regulatory Methods

Historically, many of the analyses for residues (whether drugs, pesticides or other environmental contaminants) in biological matrices were generally developed and performed on the basis of individual analytes. It was not until the advent of chromatographic techniques (paper chromatography, thin-layer chromatography, gas chromatography (GC) and high-pressure liquid chromatography (HPLC)) that multiresidue analyses began to be developed and routinely employed. The classical method developed for the analysis of chlorinated pesticide residues in foods using paper chromatography was pivotal in terms of the evolution of multiresidue analyses. The Mills’ method, which utilized solvent-partitioning techniques for compound isolation and columns (e.g. Florisil) for fractionation and sample cleanup, became the foundation of the FDA monitoring program for the analytical techniques utilized for multiple-residue analyses.

Further refinement of the Mills’ method was published in 1963 using GC and a halogen-specific detector and became known as the MOG (from the authors’ last names) method. Subsequent collaborative laboratory studies following the Mills’ method led to the publication of multiresidue methods in the Association of Official Analytical Chemists (AOAC) Official Methods of Analysis (1990) and are the basis of most multiresidue methods that are utilized today. A more thorough review of the evolution of these early multiresidue methods has been reported. For example, most methods currently being used by monitoring agencies for pesticide analysis are based on five ‘classical’ multiresidue methods, some developed over thirty years ago. These methods are commonly called the nonfatty (MOG), fatty (Mills’), Luke, Storherr and Krause methods. Together they detect over 300 pesticides or pesticide-related compounds. Most of these methods have undergone rigorous multilaboratory calibration studies, such as those needed to obtain official acceptance by the AOAC, a requirement in becoming an official method. These methods are the backbone of residue analysis protocols for the FDA, USEPA, and the NOAA. These methods work well under...

certain conditions and for certain purposes. However, perhaps the greatest drawback to their continued use is their inefficiency as screening methods. Furthermore, these methods are sufficiently complex as to not allow the generation of relevant data in time to prevent contaminated foods from entering the marketplace before a pollution or contamination problem is noted. For example, the FDA is responsible for prohibiting interstate marketing of food containing illegal pesticide residues but, in many cases, food is sold before the FDA completes the analyses.

Table 1 provides the internet addresses of agencies involved in environmental analyses in the USA.

3 METHODS AND THEIR APPLICATIONS

3.1 Sample Preparation

As noted in the beginning of this article, analysis of any sample requires rigorous preparation and consideration of a wide range of factors before proceeding to extraction. These are addressed below.

3.1.1 Documentation

It is of absolute necessity in any analytical undertaking that the analyst provide and be provided with adequate documentation. This process begins with recognition that the data must be generated using validated official methods or their equivalent if the results are to be found acceptable by the environmental analytical community. Detailed protocols for sample collection and identification, chain of custody, transfers, handling, storage, access, etc. exist and are expected to be used in any environmental analytical process. Laboratories conducting such analyses are usually certified and regularly audited to assure that they meet QA and QC guidelines and regulations, of which much is documentation.

3.1.2 Collection

There is a considerable amount of information on sample collection, including statistically derived sampling protocols, in the technical literature. Any method of sample collection attempts to ensure that samples represent their populations and that sample sizes are manageable and cost-effective for analysis. Typically, edible aquatic resources (i.e. mainly finfish, shellfish and molluscs) collected for regulatory purposes are either presented whole, as a raw agricultural commodity, or are presented as processed foods (e.g. in canned or breaded form). The same is true of other raw and/or processed commodities.

In conducting sample collection and preparation for analysis the analyst must keep in mind the many possible routes of exposure to the component parts of a target biological sample. The analyst must examine the environment surrounding the target as a whole to fully assess the contribution of air, water, soil, diet, etc. Assurances must be made that a further route of contamination does not occur; contamination by the analyst.

3.1.3 Preservation

Ideally, raw, whole samples should be analyzed directly after collection. Because analysis at the time of collection is often impossible, a few special precautions must be taken to preserve the integrity of the samples. For samples collected for environmental monitoring purposes, the USEPA recommends, for example, wrapping whole fish in aluminum foil and preserving by either icing down samples to be analyzed immediately (i.e. within 24 h) or by quick-freezing in dry ice any samples to be stored (see section 3.1.4).

An alternative method of preservation described in the literature is tissue dehydration. Homogenized molluscan tissues that are first dehydrated with a desiccant mixture (90% Na2SO4 and 10% silica) can be wrapped in aluminum foil and held at room temperature for over 15 days without degradation or loss of chlorinated pesticide residues. Whatever the biological matrix, consideration for the preservation of the sample itself and the possible pollutants contained therein must be given. Since most of the mechanisms for degradation involve heat, light, air and biological oxidation, enzyme activities and the like, freezing of the sample and wrapping the sample in a clean, non-transparent container will usually suffice to preserve the sample for transport.

3.1.4 Storage

Storage requirements vary according to how quickly residues will be extracted from the tissues. Tissues
to be extracted within 24 h may be stored at normal refrigeration temperatures (+2 to +4 °C); whereas tissues to be held for a longer period of time should be frozen (−12 to −18 °C). Whole fish may be stored for up to six months if kept in a freezer that maintains an even temperature below −26 °C. Samples may be homogenized to decrease storage space. However, if these homogenized samples are to be held for longer than a month, they should be monitored for stability of the pesticide residues of interest.

Storage containers (e.g. zip-lock freezer bags) should prevent contamination, moisture loss or gain, and oxidation, hydrolysis, isomerization, polymerization or other cause of decomposition of tissues or residues. Well-sealed containers are especially important to protect samples from desiccation in self-defrosting freezers.

In addition, samples should be individually packaged for storage to avoid unnecessary handling of tissues not immediately being analyzed. Repeated freezing and thawing disrupts cell membranes. As a result, lipids, and therefore lipophilic pesticides, such as the chlorinated hydrocarbons, may be lost from cells.

The USEPA proposes an alternative method for storing samples, which requires immediate solvent extraction of lipids and pesticides from tissues and then removal of all or most of the solvent. Extracts can then be stored at low temperatures. However, the USEPA recommends evaluating residue decomposition in this state by creating and storing spiked controls along with the sample extracts. Depending on the nature of the biological sample and the compound being targeted for analysis, different storage conditions may be required. It is of value to conduct storage stability analyses in complement to any analytical procedure. Fortification of control tissues with a range of concentrations of the target analyte(s) assayed over times that are relevant to the storage of actual samples provides the analyst with data concerning the accuracy of the final result. It cannot be assumed that simple freezing of a sample will assure stability, as many compounds will continue to degrade even when frozen at −80 °C.

3.1.5 Shipment

Samples for environmental analyses are often collected under field conditions that do not permit immediate freezing. Nevertheless, samples should be shipped frozen as described above. Samples subjected to elevated temperatures that may exist during travel could undergo rapid degradation. Such degradation may affect the chemical nature of the residues and will definitely affect lipid structure and content of tissues, possibly resulting in a loss of the residues. Changes in structure and content of samples may also adversely affect subsequent isolation procedures.

3.1.6 Stability

In general, most of the chlorinated pesticides and other compounds of interest, such as PCBs and PAHs, present in biological samples occur as relatively stable residues. For example, most DDT has been metabolized or has decomposed to 1,1-dichloro-2,2-bis[p-chlorophenyl]ethylene (DDE) (CAS 72-55-9) and 1,1-dichloro-2,2-bis[p-chlorophenyl]ethane (DDD) (CAS 72-54-8), both very stable compounds and hence, persistent residues. Most of the 16 chlorinated hydrocarbon pesticides that are regularly monitored by the USEPA have been banned for many years in the USA so are generally found in tissues as their most stable metabolite or decomposition product. Other examples include aldrin (CAS 309-00-2) and heptachlor (CAS 76-44-8), which occur as dieldrin (CAS 60-57-1) and heptachlor epoxide (CAS 1024-57-3), respectively, in tissues.

Standards of all chlorinated pesticides are necessary for residue determination and confirmation. The FDA Pesticide Analytical Manual (PAM) states that these compounds are “rather stable” and not subject to decomposition in solution. In a study to determine stability of several of these compounds (individually prepared in 2,2,4-trimethylpentane), results of GC analysis indicated no other substances other than the parent pesticides over a period of eight months. However, the manual recommends protecting all standards from UV radiation. Different recommendations will hold for the other classes of pollutants and individual compounds.

3.1.7 Processing Before Extraction

Samples generally must undergo some sort of processing procedure before the residues can be extracted. Most processing procedures are steps taken to isolate specific organs or tissue types. For some of the environmental monitoring protocols reviewed in the literature, processing includes removal of any tissue parts having direct contact with the aluminum foil or container in which the samples were stored. This step is thought necessary to prevent surface contamination of tissues.

For example, the FDA PAM includes instructions for preparing the edible portion of fresh hard shell and soft shell crabs; oysters; clams; fish; and shrimp, crayfish and other shellfish.

1. For hard shell crabs, a ‘homogenous mixture of meat and fatty materials’ is examined. This mixture is isolated by heating the crab in boiling water or steaming autoclave for one minute. The claws and other appendages are removed; meat is recovered
from them. After the back shell is removed, all meat from this location is conserved, but viscera and gills are discarded. The entire body of a soft shell crab is used for its analysis.

2. For oysters and clams, a homogenous mixture of meats and liquor is examined.

3. For fish, the following parts are discarded: heads, scales, tails, fins, guts, and inedible bones. Skin remains, and all muscle is filleted for inclusion in the sample. Muscle from very large fish may be sampled from various anatomical locations.

4. For shrimp, crayfish and other shellfish, only the edible meat is examined. All heads, tails and shells are discarded. The manual does not specify what to do with hepatopancreas (‘backfat’), which is considered to be edible in crayfish and is often included in processed packages of frozen crayfish tail meat sold in commercial markets.

Homogenizing entire organisms or first isolating the edible portions before homogenizing is very time-consuming and labor-intensive. In most cases, large (20–50 g) subsamples of these materials are used for extraction with only a portion of the extract actually being used in the final steps of analysis. New methods efficient enough to extract and quantify the amount of residue present in a small aliquot of muscle, liver, fat or other relevant biological component could be easily adapted to these procedures and could eliminate some of these inconvenient steps.

3.1.8 Quality Assurance and Quality Control

Analytical data concerning pollutant residues must be easily interpretable, unambiguous, valid and reliable in order to support the decisions made by a regulatory agency to condemn contaminated products or consider assigning an area a designation as a public health hazard. Ideally, contaminated products intended for consumption are condemned and removed before they enter commercial markets in order to limit the amounts of chemical residues entering the food supply. The presence of chlorinated hydrocarbon pesticide residues in edible aquatic species, for example, continues to cause concern because of the as yet unknown health effects of many of these chemicals. Many of the chemicals are classified as suspected carcinogens. (47)

In order to obtain acceptable data, regulatory agencies on both state and federal levels that are currently involved in environmental monitoring must use one of the few ‘approved’ methods for residue analysis. These are the methods that have undergone the rigorous multi-laboratory calibration studies necessary to achieve the AOAC Official Method status. The methods in the FDA PAM are mostly AOAC approved and designated as such in the manual. (45) Often funds are not available for developing and testing new methods even though the existing methods often fail to be simple, rapid, safe to workers and cost-effective.

For its environmental monitoring programs, the USEPA has an interlaboratory QA program which functions for state and private laboratories working under contract for either the United States Department of Health and Human Services or the USEPA. (39) The program requires all participants to periodically analyze “check samples”, samples prepared by a coordinating laboratory with an undisclosed level of residue, in order to “assess the continuing capability and relative performance” of the participant. (39) In addition, the program provides certain nonprofit laboratories with analytical-grade pesticide reference standards. All laboratories must follow the standard analytical methods in the USEPA manual (43) and use standard materials supplied by the USEPA. On-the-job training and assistance may be provided. The USEPA also runs an electronic facility for maintenance of laboratory instruments. The USEPA also utilizes a Laboratory Data Integrity Branch (LDIB) which is responsible for implementation and refinement of the agency’s GLPs compliance monitoring program.

Part of the QA of such studies is the use of primary reference standards. Primary reference standards are analytical-grade standards that are greater than or equal to 99% pure. There are several commercial sources for primary standards of the chlorinated pesticides. The standards maintained by the USEPA QA Program are no longer available free of charge to any laboratory that requests them. The USEPA standards are now only supplied to specific laboratories.

3.2 Extraction and Cleanup

This section will provide an overview of the evolution of extraction and cleanup techniques in environmental analysis of biological samples. Table 2 (48–50) is a descriptive outline of cleanup techniques. The outline is based on reviews by Walters (48) and Lott and Barker (30) on cleanup techniques for pesticides in fatty foods. The dates in the outline generally correspond to when particular techniques were first developed for cleanup of tissue extracts for pesticide analysis. Most of the techniques have been applied to clean up tissue extracts for subsequent isolation of chlorinated pesticides.

The initial approaches involved standard countercurrent, liquid–liquid extraction. These processes were complicated by the formation of emulsions, requiring lengthy procedures and addition of salts, etc., to prevent or resolve their formation. These extraction procedures also resulted in isolating both the lipophilic pollutants

and all the lipids of the sample simultaneously with little or no resolution. The introduction of sorbent materials such as Florisil and alumina that had a greater affinity for lipids over the relatively more polar analytes was a great advance in the field and greatly simplified the process of pesticide isolation from fatty samples. Removal of fats by saponification enjoyed a brief consideration but many of the pesticides were not stable to the conditions required. Steam distillation and sweep co-distillation which employed sweeping the distillate with a gas to carry the vapor into a collection tube was also found to be applicable but limited. The development of GPC greatly enhanced the ability to perform purification of biological samples for the isolation of pollutants. The procedure is discussed in detail later in this article. The evolution of other chromatographic methods, particularly SPE, also greatly enhanced the ability to perform environmental analyses in biological samples by providing more consistent materials for chromatography. The development of bonded phases that permitted a higher-resolution fractionation of extracts using a variety of phases and solvents was an immediate boon to the field. More recent developments, which will be discussed individually, are SFE, MAE, ASE, new SPE materials and devices, SPME and MSPD.

For illustrative purposes, Tables 3, 4 and 5 are outlines of the methods currently used by the FDA, USEPA, and NOAA respectively. These methods are very similar; extraction of lipids is done with solvents, lipids are removed by liquid–liquid partitioning and adsorption chromatography with Florisil, and further cleanup and fractionation of pesticide residues is usually performed with additional adsorption chromatography columns. The methods also include supplemental cleanup steps.

As mentioned previously, most analytical methods can be divided into four basic procedures: extraction of lipids and associated pesticides, preliminary cleanup of extract (bulk removal of lipids), isolation of pesticides and detection of pesticides. The separation of cleanup and isolation techniques into two different categories is not always applicable to a method. Some of the techniques, such as liquid–solid adsorption chromatography techniques, have been relied upon to both clean up and fractionate extracts with one elution.

As the preceding information indicates, there is sufficient methodological data concerning the analysis of edible aquatic species for chlorinated pesticides to formulate an opinion concerning their appropriateness and use in developing new or future directions for the field. As underscored by the General Accounting Office report of 1986, there is an existing need to dramatically increase the numbers and types of samples analyzed for chlorinated pesticides as well as other compounds in the environment. A governmental monitoring program for aquacultured and wild-caught species is also proposed for the USA and is already under way in a number of other nations. Both of these needs will foster a demand for new multiresidue methodologies that are capable of handling the expected sample load and that will do so in a cost-efficient and rapid manner.

The “official” methods presented here are based on classical techniques that have evolved through and withstood the test of time and use. Methods become classical for a reason. They work. However, these methods are not capable of analyzing an order of magnitude or more samples without producing greatly increased costs for testing and a laboratory gridlock in the effort to impose such lengthy, labor-intensive methods on a task that requires speed and reduced costs. Nevertheless, such “validated” methodology has its place in the determinative or quantitative phase of pesticide analysis and in the final confirmation of results that will be taken before a court or regulatory body. The greatest failure is their use as a screening technique, for which they continue to be used today. These methods are not sufficiently fast to provide data on a time line that includes the prevention of contaminated foods from entering the marketplace. Presently, results are obtained after the fact and penalties are levied after the ‘damage’ has been done to the consumer. Further, these methods require large volumes of solvents, many of which are of greater environmental concern than the compounds they are used to isolate. Much of this solvent is evaporated into the atmosphere, contaminating the air, or may be improperly disposed of, leading to further contamination of aquifers and aquatic habits and resources. One of the greatest costs in analysis today, other than employee costs, is the purchase price and subsequent disposal costs of organic solvents and wastes. In many cases the disposal costs of a given solvent per liter now exceeds the original purchase price. For these reasons alone the use of these “official” methods should be severely curtailed and phased out as new “official” methods are developed and validated and as new methodology for the screening of samples begins to be developed and implemented. Chemists should avoid developing methods that simply mimic these classical approaches.

Most of the information for the variety of species examined to date involves the use of “classical” or modified classical methodology. There have been recent advances in the field, however, that offer a degree of optimism concerning our ability to address these analytical problems.
Table 3 Outline of the methods used by FDA for analysis of chlorinated pesticide residues in fish

I. Extraction of fats (AOAC)
   A. Sample: 25–50 g homogenized fish (approx. 3 g fat)
   B. Homogenization of tissues with anhydrous Na₂SO₄ which:
      • combines with water
      • disintegrates sample
   C. Multiple extractions with petroleum ether (pet. ether)
   D. Cleanup of extracts and rinses with a column of Na₂SO₄
   E. Concentration (Kuderna–Danish concentrator)
   F. Lipid determination
      Note: Fish containing <10% fat may be analyzed by methods for nonfatty foods.
      Total volume of solvent used: approximately 500 mL

II. Extraction of pesticides from isolated fat and oil (AOAC)
   A. Pet. ether/ACN partitioning
      Total volume of solvent used: approximately 365 mL
   B. Florisil column
      1. Florisil and Na₂SO₄ in column
      2. 6% ethyl ether/pet. ether
      3. 15% ethyl ether/pet. ether
      4. Concentration of each eluate
      Total volume of solvent used: approximately 460 mL
      Optional or alternative methods:
   C. ACN/pet. ether backwash (optional – to improve cleanup)
      Total volume of solvent used: approximately 275 mL
   D. Partition chromatography (alternative to pet. ether/ACN partitioning)
      1. Florisil column
         a. Sample
         b. 10% H₂O/ACN
      2. Separator
         a. Eluate
         b. Pet. ether
         c. Saturated NaCl
         d. H₂O
      3. Anhydrous Na₂SO₄
      4. Kuderna–Danish concentrator
      Total volume of solvent used: approximately 181 mL

III. Supplemental cleanup
   A. 6% eluate
      1. +/- GLC or thin-layer chromatography without further cleanup
      2. +/- Second Florisil column (AOAC)
         Total volume of solvent used: approximately 460 mL
      3. +/- Acid–Celite column (AOAC: DDT only)
         Total volume of solvent used: approximately 85 mL (more if sample contains more fat)
   B. 15% eluate
      1. +/- MgO–Celite (AOAC)
         Total volume of solvent used: approximately 140 mL
      2. +/- Alkaline hydrolysis (AOAC)
         Total volume of solvent used: approximately 50 mL
      3. +/- Alkaline hydrolysis followed by MgO–Celite

IV. Determination
   A. GLC/electron capture detector
   B. Confirmation:
      1. Initial test: thin-layer chromatography
      2. Others
Table 4 Outline of the methods used by the USEPA for analysis of chlorinated pesticide residues in human and environmental samples

I. Extraction of fats
   A. Sample: 5 g
   B. Dry maceration with sand and anhydrous Na$_2$SO$_4$
   C. Addition of aldrin as a quantitative recovery check
   D. Multiple extractions with petroleum ether (pet. ether)
   E. Evaporation to dryness for lipid determination
      Total volume of solvent used: approximately 160 mL

II. Liquid–liquid partitioning
   Pesticide residues are extracted from the fat with ACN and then partitioned back into pet. ether by aqueous dilution of the ACN extract.
   A. Solvents: ACN, 2% NaCl, pet. ether
   B. Drying with anhydrous Na$_2$SO$_4$
   C. Concentration (Kuderna–Danish concentrator)
      Total volume of solvent used: approximately 365 mL

III. Florisil fractionation
   A. Florisil and anhydrous Na$_2$SO$_4$ in column
   B. 6% diethyl ether/pet. ether
   C. 15% diethyl ether/pet. ether (with addition of aldrin to this fraction) +/− MgO–Celite column chromatography afterwards
   D. Concentration of each eluate
      Total volume of solvent used: approximately 461 mL
      (MgO–Celite chromatography would require an additional 140 mL of solvent.)

IV. GLC/electron capture detector determination

Table 5 Outline of the methods used by the NOAA for analysis of chlorinated pesticide residues in tissues

I. Extraction
   A. Sample: 3 g
   B. Homogenization with internal standards and Na$_2$SO$_4$ and 3 extractions with DCM
   C. Centrifugation (repeated 3 times in conjunction with the extractions)
   D. Concentration with boiling chips
      Total volume of solvent used: approximately 80 mL

II. Silica gel/alumina column chromatography
   A. Alumina, silica gel and sand in column
   B. Pentane
   C. 50% DCM/pentane
   D. Concentration of each eluate
      Total volume of solvent used: approximately 246 mL

III. Sephadex LH-20 Chromatography
   A. Second fraction only (50% DCM/pentane)
   B. Concentration of eluate
      Total volume of solvent used: approximately 235 mL

IV. Determination
   A. GLC/electron capture detector
   B. GLC/mass spectrometric detector confirmation

DCM, dichloromethane.
4 NEW APPROACHES TO SAMPLE PREPARATION AND CLEANUP FOR ENVIRONMENTAL ANALYSES

4.1 Gel Permeation Chromatography

A property of solids can be the presence of holes or pores in the surface, part of the very structure of the materials, that permit penetration or permeation of certain size molecules while excluding others. Thus, this size exclusion or permeation process can be used to fractionate materials by size, using smaller pores to trap or retard smaller molecules and increasingly larger pores to retain or slow increasingly larger, higher-molecular-weight species. Such materials can be said to possess molecular-weight ‘cut-offs’, retaining molecules below the stated value while permitting the elution of species above this value, acting, essentially, as molecular sieves. This process is not highly specific, however, and lacks resolving power, with overlap of a variety of similar molecular-weight species and, of course, much greater molecular-weight species. Nonetheless, as an approach to roughly separating lower- (such as pesticides and herbicides, MW range of 200–400 amu) and higher- (proteins, carbohydrates, triglycerides, etc. MW range of 600 or greater) molecular-weight species it can often prove to be a useful and powerful technique. This application has been enhanced by the development of automated systems.

Both natural and manufactured materials of defined pore sizes are available. These materials have the appearance of gels when in the presence of solvent, and the process has been given the general name of GPC. These gels are, as might be expected, subject to damage by high pressure and one must be careful to match the permeation material with the appropriate solvent. Newer materials are available for use with higher pressures and are beginning to incorporate surface chemistries that provide a further level of interaction with matrix and target analyte components that enhances the technique for certain applications. The most common materials employed are divinylbenzene-linked polystyrene beads of a 200–400 mesh size.

GPC, especially with the development of automated systems, has found renewed use for the fractionation and cleanup of biological samples for environmental analyses. It has also been used as an adjunct to the extraction and cleanup of samples following isolation of the target analytes by SFE as well as accelerated solvent and MAE techniques. Fractionation of target analytes from the large lipid band from high-fat samples is not always completely successful and additional cleanup steps are often required. These usually involve adsorptive or bonded-phase SPE techniques. Table 6 offers a list of applications and reviews for GPC in environmental analyses.(53–66)

4.2 Supercritical-fluid Extraction

If gases are maintained at specific conditions of pressure and temperature they will exist in a state known as the supercritical (SC) phase. Under these conditions the gases exist as liquids and can be used in the same manner as other solvents. Since most gases are nonpolar in character, the SC gas can be used as a nonpolar solvent to extract nonpolar analytes from samples. Removing the SC conditions, such as lowering the pressure or raising the temperature, causes the gas to return to its original state. Thus, if we use carbon dioxide (CO2) from the atmosphere, compress it to a SC state and use it as an elution solvent to isolate compounds from a sample matrix, we can eventually ‘dispose’ of this solvent by letting it go back whence it came. Modification of the polarity of the SC gas to obtain a better or more selective extraction can be accomplished with the addition of other gases or, more commonly, the addition of small amounts of “normal” solvents, such as methanol, to the SC phase. This provides a high degree of flexibility and more selectivity to the technique. Extraction efficiency in SFE also varies with temperature, pressure, SC fluid flow rate, extraction vessel dimensions, sample water content and a variety of other condition variables.

With the SFE technique carbon dioxide (SC-CO2) is commonly used as the extraction medium in place of organic solvents. Chlorinated pesticides and associated lipids are soluble in SC-CO2. They can be extracted from tissues and then collected once the pressurized CO2 is brought back to atmospheric pressure. This may be accomplished by collection of the SC gas in a solvent or trapping of the analytes by passing the eluate through a solid surface support material. The main advantage of this
technique is that expensive, flammable, and potentially hazardous organic solvents are not used in quantity. However, because the extracts contain contaminating lipids, a cleanup step is usually needed before samples can be injected onto a GC apparatus. Cleanup can be performed with a variety of chromatographic techniques, such as GPC or adsorption chromatography with Florisil, for example.

Water in the sample can interfere with the extraction process and variable water content from sample to sample can confound analytical results. This problem has been overcome with the development of a protocol that calls for first mixing samples with diatomaceous earth and other dessicants (silica, for example) before extracting with SC-CO2. This step disperses the sample material and allows adsorption of water before extraction with SC-CO2 or other suitable SC-solvent.

A drawback to the use of SFE is the initial capital outlay required for the equipment and the limits on the number of samples that can be processed in a batch. Newer equipment is becoming less expensive and more efficient for sample throughput and such concerns must be balanced against the savings incurred from not having to purchase and dispose of large volumes of organic solvents.

Table 7 is a list of applications of SFE to isolation of pollutants from biological samples. An excellent general review of SFE has also been published.

4.3 Accelerated Solvent Extraction

The chemist can increase the rate of interaction of one molecule with another by increasing temperature which is, after all, a measure of relative motion. This increased motion in a closed system results in increased pressure. Thus, if we place a sample in contact with an extracting solvent in a closed system and elevate the temperature and the pressure, we will obtain a greater degree of interaction of the solvent with the sample. This process may translate into more efficient extractions, requiring less solvent and time. This is the case and such procedures have been applied in the form of automated systems performing what has come to be known as ASE. This is also a drawback to ASE; the initial outlay of funds to purchase the equipment. The analyst must assess such cost-effectiveness against sample load, solvent costs, employee costs and savings and turnaround time.

References for the use of ASE on biological samples specifically are limited at this writing. Obana et al. have, however, reported the isolation of up to 19 organophosphorus pesticides at 0.1 ppm or less from four different foods using an ASE instrument operating at 100 °C and 1500 psi in less than 20 minutes. As in SFE, samples were mixed with a drying agent prior to ASE and the extract was cleaned up using GPC prior to instrumental analysis.

4.4 Microwave-assisted Extraction

Microwave heating for sample dissolution in elemental analysis has been a recognized technique for over two decades. The application of microwave irradiation to the extraction of compounds from biological samples has been a more recent development. In general, samples are homogenized and mixed with a solvent and the suspension irradiated at greater than 2000 MHz for short periods of time. Heating is usually repeated several times with periods of cooling in between to prevent boiling. The efficiencies seen with this technique approach those of classical Soxhlet extraction but can be performed much more rapidly. Further modifications of the technique mimic sweep co-distillation or steam distillation with air sweeping the surface of the heated sample and being collected by a condenser that protrudes through the oven housing. Techniques have also been developed using
closed-system microwave heating. The major advantages of MAE are shorter extraction times and reduced solvent use.\(^{94}\) Ganzler et al.\(^{95}\) have reported the extraction of a variety of compounds from seed, foods and feeds, finding the process to be more efficient than classical Soxhlet or liquid–liquid partitioning extraction. Ren and Desmarchelier\(^{96}\) applied the technique to the isolation of fumigants from grain, releasing the fumigants into a sealed-system headspace by microwave heating and assaying the headspace. The technique has also found application in the isolation of biomolecules\(^{97}\) and in conducting environmental analyses in soils, sludge and other non-biological matrices.

### 4.5 Solid-phase Extraction

The use of the inherent chemistry of the surface of particulates such as silica, Florisil, sodium sulfate, etc. to interact with and assist with the isolation and purification of a variety of pollutants in different matrices, or the process of SPE, has been the backbone of many of the classical methods for performing environmental analyses on biological samples. In the SPE process, a compound is isolated from a liquid sample based on its relative solubility in the liquid mobile phase compared to its solubility in a solid support or a modified solid-support/bound-liquid stationary phase of differing polarity. Isolation is accomplished by passing the analyte dissolved in solvent (organic or aqueous) through a column containing the stationary phase with subsequent elution using an appropriate solvent. Several SPE methods have been developed to facilitate the extraction and cleanup of biological liquid and tissue samples.

For liquid matrices, such as blood plasma or serum, acceptable residue recovery may be obtained using protein precipitation and direct injection without cleanup, but the many impurities present can affect the chromatogram and accumulate on the analytic column, thus resulting in increasing back pressure. SPE cleanup helps avoid these problems and works well with biological fluids such as plasma, urine and cerebral spinal fluid. In addition, SPE extraction and analysis can be automated and done on-line and/or with on-line dialysis and column switching. Before SPE can be used with solid tissue (e.g. muscle and liver), a separate homogenization step and often multiple filtration, sonication, centrifugation and liquid–liquid cleanup steps are required. While SPE may improve cleanup of these solid tissue samples, the additional labor and materials costs make SPE less suitable, in some cases.

SPE methods published for solid biological samples are often combinations of SPE with other methods such as homogenization, liquid–liquid partition, filtration, sonication and centrifugation. Because choice of SPE column depends on the matrix and on the particular compound of interest, a wide range of solid-phase columns of differing polarities have been used for extraction in biological samples and include C\(_2\), C\(_6\), C\(_{18}\), NH\(_2\), amberlite resins, and polystyrene–divinylbenzene polymers as well as materials that constitute the category of materials for adsorption chromatography.

#### 4.5.1 Adsorption Mode

This mode of solid-phase interaction relies on the inherent surface chemistry of a given material, the functional groups naturally available on the surface. Materials such as alumina (Al\(_2\)O\(_3\)), Florisil (an activated magnesium silicate), silica (SiO\(_2\)) or silicic acid (silica gel; H\(_2\)SiO\(_3\)), activated charcoal (carbon), etc. can provide such adsorption surfaces. Florisil is perhaps the most often used sorbent in environmental analyses because of its capacity to adsorb fats. Using solvents of low polarity for elution, relatively nonpolar residues can be isolated with high efficiency. Florisil must be activated, however, by maintaining a certain percentage of water. Variability in this value can lead to erratic results. In many cases Florisil can be replaced by alumina. However, basic alumina will lead to the decomposition of some organophosphates and can be highly retentive of more polar target analytes. The silicas have found less general use but have been employed to perform fractionation of more polar constituents in complex extracts from the less polar components.

Extracted samples in solution may be percolated or passed through columns of such materials to obtain a differential distribution of target analytes from other components between the immobile solid phase and the mobile liquid phase. In this manner, target analytes may be retained on the column while co-extracted interferences pass through or are washed from the column by addition of another volume of the same or different solvent. Conversely, the target analytes may be made to pass through while undesirable compounds are retained. Often one sees both and a bit of overlap.

A number of such materials are also manufactured, often in the form of resins, that possess ionic surface chemistry characteristics. These materials may contain an intrinsic negative charge (sulfate, phosphate, etc.) capable of bonding or exchanging positive-ion-containing species or may contain a positive charged surface (quaternary amines, for example) capable of ionic bonding or exchange with negatively charged compounds. The ability to exchange ions using such surface chemistry, thus leading to greater retention of compounds undergoing such exchange, is useful in isolating and resolving charged species from neutral or weakly ionized compounds.

We should also note here that, especially in food chemistry, a number of solid sorbents have been used...
to assist in ‘drying’ the sample. This is accomplished essentially by adsorbing the water in the sample matrix into a solid material such as diatomaceous earth (silica) or sodium sulfate by blending the materials together. Such an approach is used today to conduct SFE, ASE and Soxhlet extraction of homogenized samples. The adsorptive properties of diatomaceous earth blended with the sample eliminates complications due to the presence of water in such extractions. It also provides a level of interaction of the sample and the target analytes with the surface chemistry of the dessicant. Further, solid materials such as sand (silicates) have been combined with samples to serve as an abrasive, using the materials to assist in the disruption of sample architecture through blending or grinding. These agents also have a surface chemistry which may interact with the sample to varying extents.

The sample matrix itself is always a significant contributor to loss of target analytes owing to electrostatic and/or covalent or ionic interactions, much as occurs in the use of sorbent technology. Indeed, the solid sample matrix is the surface chemistry that the analyst must initially deal with in terms of obtaining efficient isolation of analytes, breaking protein binding or ionic interactions of analytes with matrix components. Homogenization of a sample with solvent, extraction by Soxhlet solvent reflux, etc. are extraction/fractionation processes that are controlled by interactions of the analytes with the sample matrix components, the sample’s own surface chemistries. These chemistries are far more complex than simple adsorption, however, and cover the entire range from affinity binding (receptor-bound target analytes) to size exclusion, to adsorption and phase distribution.

### 4.5.2 Bonded-phase Partition Mode

While the use of solids in the adsorption mode does provide a range of chemistries for a variety of applications it does not always provide sufficiently adequate interactions to resolve very similar chemical entities. Thus, alteration of the surface chemistry by derivatization of the functional groups present on the surface with a variety of chemically unique compounds offers the ability to provide an even greater range of interactions that can be brought to bear on a given analytical problem. Solid materials that are commonly used for such purposes have been silica, with available silanols for derivatization, and synthetic polymers such as polydivinylbenzene or polystyrene, which can be chemically modified or initially formed to provide other functionalities.

The derivatizing agents to be used to prepare such surfaces can be designed so as to provide a range of surface chemistries, highly polar to highly nonpolar, high carbon content, low carbon content, cross-linked, etc. that make such materials applicable to a variety of analytical problems. The covalent bonding of the agent to the solid material provides a phase that is immobile or stationary, one that cannot be readily eluted from the material. Thus, this stationary phase can be used, essentially, as an immobile solvent in which sample components can be partitioned. This provides a mechanism for distribution of analytes and other sample components between this stationary “solvent” and the solvent in which the sample is dissolved and applied to the material, and the solvent subsequently applied to the material in an effort to selectively elute analytes or potential interferences.

#### 4.5.2.1 Normal Phase

A polar stationary material (or phase). Application of a sample will lead to retention of polar sample components and analytes while nonpolar species will be readily eluted or will pass through the material without retention. Washing with nonpolar solvents will clean the column of such nonpolar sample components or, depending on whether one seeks retention of target analytes, permit further isolation of nonpolar analytes in the eluate. Removal of retained material will require solvents of increasing polarity and/or the use of changes in pH or ionic strength, depending on the nature of the stationary phase and analyte interactions. Examples of normal-phase materials are derivatized silica, and diol-, cyano- and amine-containing derivatives.

#### 4.5.2.2 Reversed Phase

A nonpolar stationary phase. Application of a sample will lead to retention of nonpolar sample components while polar species will be permitted to pass through. Washing the column with more polar solvents will further remove the more polar components while removal of the retained species will require less polar solvents, thus, a reversed condition compared to normal phase. Examples of reversed-phase materials are ethyl, butyl, octadecyl, octyl, cyclohexyl or phenyl derivatives.

#### 4.5.2.3 Ion Pairing

A nonpolar stationary phase in the presence of an ion that counters the charge of the ion(s) present on the analyte, thus making it neutral and more interactive with the stationary phase; e.g. using tetraethylammonium ions to counter negatively charged functional groups on a target analyte.

#### 4.5.2.4 Ion Exchange

A stationary phase containing ionizable functional groups, ranging from strongly to weakly ionized. Application of a sample containing target analyte cations (positive charges) will cause such compounds to be retained by a stationary phase containing anions (negative charges) and vice versa. The material may be washed with organic or aqueous solutions containing no ions or ions of lower ionic strength that will, thus, not exchange for the ions retained. Retained
compounds are eluted with organic solvents or aqueous solutions containing ions of greater ionic strength than those bound to the stationary phase of the column. Some examples of ion-exchange materials are those derivatized with amino groups that are or can be readily quaternized (triethylaminopropyl (SAX); diethylaminopropyl (DEA)) or species carrying a negative charge (benzenesulfonylpropyl (SCX); sulfonylpropyl (PRS); carboxymethyl (CBA)).

4.5.2.5 Mixed Modes  All sorbent materials are capable of exhibiting some or all of the characteristics described above. As previously mentioned, underivatized silanols on silica-based sorbents give the material both an adsorptive character that is associated with a normal phase and the intended character of the existing derivative, whether normal phase, reversed phase, ion pairing or ion exchange. Furthermore, many of the derivatives that are used to provide the more polar functionalities are covalently bonded to the silica surface through a C–H-containing chain that may be 1–8 carbons in length. Thus, molecules may undergo ionic interactions, lipophilic or hydrophobic interactions and/or adsorption to underivatized functional groups on the solid support all at the same time. This depends, of course, on the structure of the analytes and the other myriad matrix components. Interaction of target analytes with retained matrix components which are interacting with the solid support/stationary phase is also part of the consideration of the overall mixed-mode interactions taking place.

In all forms of sorbent technology one seeks to obtain varying degrees of retention and elution for the target analytes and other matrix components relative to one another, to take advantage of the relative selectivity of the sorbent and the method applied. This is under the control of several variables, such as the chemical structure of the analytes, the characteristics of the sorbents, the composition of the sample matrix and the solvent-elution conditions or profile selected. Maximum retention or selectivity for a given analyte occurs when the structure and chemistry of the analyte most closely matches that of the sorbent while all other components are divergent from this condition.

The capacity of the sorbent material, its ability to retain a relative quantity of material per gram or milligram of sorbent, must also be considered. This may range from 1–5% of the mass of sorbent (1–5 mg per 100 mg, for example) but this quantity must also take into consideration the fact that matrix components may also be retained on the column. Retention of large quantities of matrix components are from the analytes, the higher the resolution of components in the final eluate.

In all cases the analyst should keep in mind that a large range of variables and possible compositions of materials (sorbents, solvents, pH conditions, etc.) are available for addressing an extraction/analysis problem through the use of sorbent technology and procedures. Several chemically opposite approaches may ultimately work for a given problem.

SPE has played a major role in the development of methodology for the analysis of pollutants in water, with many of the methods now prescribed by the USEPA involving the use of this technology. Table 8 illustrates many of the applications of this process for the isolation of pollutants from biological samples.\(^{53,58,62,63,83,98–125}\)

### 4.6 Solid-phase Microextraction

Miniaturization of sorbent technology and the concomitant decrease in solvent (purchase, exposure, disposal)
has also taken a further giant step with the development of SPME devices. In this technology a fused silica fiber coated with polyacrylate, polydimethylsiloxane, Carbowax or otherwise modified bonded phase (addition of other sorbents) is placed in contact with a liquid sample, exposed to the vapor above a sample (solid, liquid) or placed in the stream of a gaseous sample. In such a manner SPME has been used most frequently to analyze volatile and semi-volatile compounds and may be used to replace purge-and-trap procedures. In relation to food chemistry SPME has proven to be particularly applicable to flavor and aroma analyses. While the technique has yet to be extensively applied to analysis of pollutants in biological samples it does, nonetheless, have great potential for such applications.

SPME is based on a simple principle that applies to all sorbent technologies; the materials in the sample will establish an equilibrium with the solid phase, based on their relative distribution coefficients. This does not require complete extraction of the compounds present but rather a representative sample that can be related to samples of known concentrations. Such samples can be readily quantitated by conducting similar exposures to standards of known concentration. The most interesting aspect of this technology involves the ability to use the exposed fiber as both an extraction and a sample delivery device, using specially designed interfaces to place the fiber in-line for GC or LC desorption or elution of analytes. Phases for SPME are available in a range of polarities and properties for application to analyses of volatile and semivolatile compounds as well as for possible applications to extraction of analytes from liquid samples. However, direct application of the method to biological samples for environmental analyses is, at present, lacking.

One of the limitations of SPME is the low capacity of the fiber and the perturbation of equilibria that can occur in the presence of sample components or analytes at very high concentration versus those of lesser concentration. Dilution of the sample can overcome some of these problems but not all, as limits of detection for trace analytes are compromised.

4.7 Matrix Solid-phase Dispersion

Another technique recently developed and applied to biological samples is MSPD. This technique is basically a simple two-step procedure for the extraction, cleanup, and isolation of pesticide (and other chemical) residues from any type of sample matrix (e.g. whole oyster homogenate, fish muscle, milk, fruits, vegetables, etc.). In general terms, the process involves blending a tissue sample (0.1–1.0 g) with lipophilic polymer-derivatized silica particles (e.g. ODS-derivatized silica (C$_{18}$), which simultaneously disrupts and disperses the sample. This mixture of C$_{18}$ and tissue becomes part of a potentially multiphasic column that possesses unique chromatographic character. Elution of the MSPD column with a solvent or solvent sequence can provide a high-resolution fractionation of target analytes that can be further purified by simultaneous use of co-columns of Florisil, silica or alumina. The final eluate can, in most cases, be directly analyzed or further concentrated or manipulated to meet the demands of the individual analysis. The extracts obtained from these methods are most often detected by HPLC (in the case with drugs) or gas–liquid chromatography (GLC) with electron capture detection (ECD) or mass spectrometry (MS) (in the case with pesticides). However, they can also be used in immuno- or receptor assays.

Additionally, the MSPD process can be modified for a particular application by

1. a change in the ratio of sample to stationary phase support;
2. use of a different polarity polymer or solid support; and
3. blending of the C$_{18}$/tissue in the presence of modifiers such as chelators, acids, bases, etc.

MSPD could also be used in conjunction with SFE. The water in biological matrices often interferes with the SFE extraction process and analysts have used samples blended with diatomaceous earth to remove water from the sample. However, blending samples first with polymer-coated silicas, as is done in the MSPD process, would remove water and provide an initial stage of fractionation at the point of elution of the analytes with SC fluid and modifiers.

In most cases, eluate samples obtained after MSPD may be directly analyzed by GC without further cleanup. This technique is rapid, simple and inexpensive because it eliminates supplies and separate steps needed for:

1. sample preparation (e.g. blenders or tissue homogenizers);
2. lipid and pesticide extraction (e.g. large volumes of solvents and filtration steps);
3. extract cleanup and pesticide isolation (e.g. more solvents and perhaps adsorption chromatography); and
4. extract concentration (e.g. N$_2$ and various types of evaporation apparatus).

Three of its main advantages are that

1. it considerably decreases solvent use compared to the “official” methods;
2. it allows for a rapid turnover of samples and hence, access to relevant data on the pesticide residue levels present in the samples; and
3. it is amenable to robotics automation.
It should be evident from this discussion that methods development for residue determination should focus on rapid screening tests, multiresidue capabilities, metabolite detection and improved sensitivity. The development and use of determinative methods for isolating the compound(s) of interest from biological samples must be rapid and inexpensive, and not generate large volumes of solvents for disposal. Classical or official isolation methods using homogenization and/or liquid–liquid partitioning of biological samples may be sufficient for some applications, such as the generation of data that will withstand a court challenge, but are poor for screening purposes because they are often lengthy, involve multiple steps and use large volumes of solvents. Such methods should not be used, as they are at present, to screen samples to determine a problem.

Solvent disposal is becoming increasingly expensive and environmentally unsound. Therefore, methods using low solvent volumes are desirable. A main purpose of this article was to present a case for phasing out the chlorinated pesticides and many other pollutants that require less sample, less solvent, less employee time and less cost per sample. Newer techniques such as SC fluid extraction, SPE and MSPD offer alternative isolation strategies. When compared to the classical methods, these new methods greatly reduce labor and solvents costs and improve throughput. There are a few drawbacks to the new methods and more work is needed to further develop SPE, SFE, ASE, MAE, SPME and MSPD for use with the many different types of matrices that may contain residues of chemical contaminants. Nonetheless, these methods show tremendous potential. For example, MSPD, when compared to classical methods, has been estimated to reduce solvent use by approximately 98% and analysis time by 97%. Furthermore, once the MSPD column is prepared, the process of solvent elution, collection and analysis can be automated by the use of robotics. Cost of analysis is decreased because less solvent is needed and fewer laboratory technicians need to undergo training. Safety and environmental protection are increased because less solvent is needed. Finally, data are generated more quickly because of the ease of the process and its potential to be automated. These features of MSPD make it a general and perhaps significantly useful method in designing future residue analysis screening programs.

By reducing the sample size, smaller quantities of solvents are needed and less total lipid and co-eluates are present. However, less total analyte is also present. The advantages are that it requires less manipulation, if any, to cleanup the sample and that the capacities of subsequent SPE or adsorption chromatographic materials are not overwhelmed by the quantities of co-extracting interferences that are therein removed. This allows the final extract to be taken up in a smaller final volume, which compensates for the smaller sample size as compared to classical methods. Given that the regulatory levels for the chlorinated pesticides and many other pollutants are relatively high, the use of a smaller sample does not compromise the analytical result. Similarly, larger sample sizes (10 g) of biological materials have been extracted for chlorinated pesticide analysis by blending with solvent and cleaned up using a sequence of SPE columns to give excellent results. These approaches offer a potentially automatable mechanism for the more rapid extraction of the chlorinated pesticides while simultaneously reducing solvent use, overall costs and data turn around time. The extracts obtained from these methods can be screened by gas–liquid chromatography/electron capture detection (GLC/ECD) or gas–liquid chromatography/mass spectrometry (GLC/MS). However, they could also be used in screening formats based on immuno- or receptor assays.

Biotechnology will be the field that will most greatly advance and revolutionize analytical chemistry in the near future. Theoretically, the chlorinated pesticides could be assayed by molecular probes or enzyme/receptor-based electrodes inserted directly into the sample. However, until such technology is fully available, we may apply the growing field of immunology-based detection and quantitation systems to assist us in solving the problems presently inherent in conducting environmental analysis. As described here, there are

5 METHODS FOR THE FUTURE

---
presently several commercially available immunoassay kits for the screening and/or quantitation of some of the chlorinated pesticides, certain herbicides and other pollutants. Others could be developed if the market for them is created. Such technology, coupled with rapid isolation procedures such as MSPD or SPE, would allow the analyst to determine the presence and the relative level of contamination of hundreds of samples in a short time frame, especially in comparison to similar screening conducted for the same number of samples by GLC/ECD, GLC/MS, supercritical-fluid extraction/mass spectrometry (SFE/MS), or other instrumental methods of analysis. However, the reliance on such technology will require a complete understanding of the assay’s specificity, sensitivity and susceptibility to false positive and/or false negative results. This is not a trivial task but can be accomplished with the proper conjunction of academic, industry, and regulatory agency input and support. The development of these technologies could also produce immunoaffinity column materials that could be used to provide a solventless extraction system for the overall analysis.

Since there is a large variety of biological samples that will require monitoring, it is unlikely that any one approach will be completely applicable to all environmental analyses. Each will require a degree of modification for a given application. However, it is evident that existing official methods should be phased out in favor of newer technologies that require less sample, less solvent, less employee time, and less cost per sample. This article offers a summary of the existing methodology for the analysis of biological samples for compounds of environmental concern and offers an opinion on the future directions for the field. In this age of environmental concern and the recognition of our environmental difficulties and our culpability in them, it is hoped that this information will serve to further the effort to define and ameliorate our past environmental misdeeds.

ACKNOWLEDGMENTS

The author wishes to acknowledge the many contributions of his graduate students to research on MSPD and its applications and their reviews of the literature related to the content of this article; Dr Patricia Gaunt, Dr Michael Crouch, Dr Calvin Walker and Dr Heidi Lott (deceased). Special acknowledgments are extended to Dr Austin Long, the co-inventor of MSPD during his tenure as a post-doctoral fellow, and to Dr John O’Rangers of the Center for Veterinary Medicine of the US FDA, the agency monitor for the research support awarded to our laboratory and gratefully acknowledged here.

Capillary Electrophoresis Coupled to Inductively Coupled Plasma-Mass Spectrometry for Elemental Speciation Analysis

Xiaoru Wang

Hong Kong Baptist University, Hong Kong, China

1 Introduction

Trace elements play a key role in the functioning of life on earth. They can be either highly toxic or essential to life depending not only on their total concentration levels, but just as important, also on the particular chemical forms in which they exist in the system. The latter information is of additional significance in environmental studies since, besides biological and toxicological concern, the transport and fate of trace elements in the environment is also highly ‘species’ dependent.

Speciation analysis is a term commonly used to describe the analytical processes of identifying and measuring the different chemical forms of trace elements in the sample. Starting from the mid-1980s, analytical techniques for elemental speciation analysis have been advancing at an accelerated pace owing to the rapid advancement in analytical instrumentation. Such advancement is especially evident in the development of hyphenated techniques, which involve the on-line coupling of a species-specific separation device with an elemental-specific detection system. They are now well accepted as the methods of choice for speciation analysis because of their speed, sensitivity, specificity and resolution. Capillary electrophoresis/inductively coupled plasma mass spectrometry (CE/ICPMS) is one of the newest members of this family of hyphenated techniques which has found increasing applications in speciation analysis in recent years. Until today, chromatography has been the dominant separation technique in hyphenated techniques and the subject has been extensively reviewed. However, literature information on capillary electrophoresis (CE)-based hyphenated techniques is much less available. In this chapter, the current status of CE/ICPMS will be reviewed with emphasis being placed on the interface design, analytical performance and applications of the different versions of the technique in speciation analysis.

1 INTRODUCTION

Trace elements play a key role in the functioning of life on earth. They can be either highly toxic or essential to life depending not only on their total concentration levels, but just as important, also on the particular chemical forms in which they exist in the system. The latter information is of additional significance in environmental studies since, besides biological and toxicological concern, the transport and fate of trace elements in the environment is also highly ‘species’ dependent.

Speciation analysis is a term commonly used to describe the analytical processes of identifying and measuring the different chemical forms of trace elements in the sample. Starting from the mid-1980s, analytical techniques for elemental speciation analysis have been advancing at an accelerated pace owing to the rapid advancement in analytical instrumentation. Such advancement is especially evident in the development of hyphenated techniques, which involve the on-line coupling of a species-specific separation device with an elemental-specific detection system. They are now well accepted as the methods of choice for speciation analysis because of their speed, sensitivity, specificity and resolution. CE/ICPMS is one of the newest members of this family of hyphenated techniques which has found increasing applications in speciation analysis in recent years. Until today, chromatography has been the dominant separation technique in hyphenated techniques and the subject has been extensively reviewed. However, literature information on CE-based hyphenated techniques is much less available.

In this chapter, we attempt to provide a capsule review of the current development of CE/ICPMS technique. The emphasis will be placed on the interface design, analytical performance and applications of the different versions of the technique in speciation analysis. The principles and
instrumental details of the individual CE and inductively coupled plasma mass spectrometry (ICPMS) instruments themselves will not be covered since the subjects can be readily found in many books or review articles.

2 CAPILLARY ELECTROPHORESIS IN SPECIATION ANALYSIS

The species of principle interest in speciation analysis include organometallic species, biological macromolecules, and organic or inorganic complexes of metals (Pb, Hg, Cr, Cu) or non-C elements (As, Ge, S). In environmental samples, these species are usually present at trace levels in highly complex matrices. For such analysis, the use of hyphenated techniques in an on-line fashion is preferred because the closed systems employed minimize the risk of contamination and losses of analysts during analysis. Among the variety of hyphenated techniques developed, the coupling of chromatography-based separation with atomic spectrometric detection are the most widely used ones.

Chromatography in its various forms including gas chromatography (GC), ion chromatography (IC) or high-performance liquid chromatography (HPLC) has been used extensively as the separation technique in speciation studies. In chromatographic separation, however, the stationary phases often interact with the analytes, resulting in the alteration of the original distribution of species in the sample. This problem is especially serious in the speciation of inorganic, metal-containing analytes because most of them are not amenable to chromatographic columns. In CE, the electrophoretic separation is applied in free solutions. There is minimum interaction of the analytes with the capillary wall or the stationary phases, since the separation capillaries are mostly made of inert fused silica tubing. Thus, the preservation of the original bondings of the species is often achievable with the proper selection of buffer solutions. Since the separation of analytes is carried out in the aqueous phase, it allows the analysis of labile species by direct injection of the sample without prior derivatization, as is often needed in GC or HPLC separations. This is particularly useful for the analysis of aqueous samples since derivatization could result in sample losses due to incomplete reactions or handling.

The separation mechanisms of CE and chromatography are completely different; the two are therefore complementary to each other in speciation applications. The versatility of CE is demonstrated by its ability to separate a wide range of ionic or neutral species including small inorganic cations or anions, organometallic compounds, organic molecules as well as large biological molecules such as peptide and proteins. The ability of CE to analyze large biological molecules is another crucial factor stimulating our interest in CE because the bindings of metals to peptides and protein enzymes in plant, animal and human tissues have important ecotoxicological implications in environmental studies.

The other attractive features of CE are that the technique is straightforward in principle, easy to operate and simple in experimental set-up. In a typical experiment, the components of a mixture are transported through a horizontal capillary tube by applying a high d.c. potential. A buffer-filled capillary is placed between two containers filled with the same buffer. Typically the tubing is fashioned from fused silica or inert polymeric tubing with a length of 50 to 100 cm and an inside diameter of 25 to 100 µm. Platinum foil electrodes in the two buffer vessels are connected to a d.c. power supply capable of developing a potential of 20 to 30 kV. Electroosmotic flow (EOF) occurs in the capillary where the solvents move from the vessel containing the positive electrode to the one containing the negative. The cause of EOF flow is the electric double layer that develops at the silica capillary surface. The fixed negative charges on the capillary surface arise from the dissociation of functional groups on the surface of the capillary. The negative surface charge attracts positive ions from the buffer solution, thus giving a typical double layer structure. The mobile positive ions that ring the interior surface of the capillary tubing are attracted to the negative electrode, carrying with them the solvent molecules. The analytes are separated by their differences in electrophoretic mobility, with the positive species moving towards negative electrode at velocities faster than EOF; while the negative ones moving slower than EOF. The neutral species, which move with the EOF flow, can also be made to separate by the selective addition of surfactants or other modifiers to alter the surface charge of the analytes.

Of the different modes of CE separation techniques, CZE (capillary zone electrophoresis) is the most widely used in elemental speciation analysis. Molecular separation in CZE is based on the difference in the electrophoretic mobilities of the species, which is proportional to the charge of the analyte, and inversely proportional to the frictional forces encountered by the analytes during elution. The latter are determined by the hydrodynamic size of the analytes and viscosity of the medium. Solvent properties such as pH, ionic strength, viscosity are all important parameters because they affect the effective charge on the solute; and for large molecules, also their effective hydrodynamic sizes. CZE has been used widely for the separation of inorganic cations, anions as well as organometallic species. Since cations with the same charge and hydrodynamic radius are often inseparable, a weakly complexing ligand can be added to enhance

selectivity and separation efficiency. Many organic compounds with electron-donating properties can be used as weak charge transfer complexes with metals for such applications. Significant advancement has been made to exploit various chemical techniques of complexation, ion-pairing, and micellization interactions between the metal analytes and electrolyte additives to enhance separation or alter selectivity.

Conventional reversed-phase liquid chromatography (RPLC) ion-pairing reagents, ionic polymers and dicarboxylic acids have all been effectively used to enhance CZE separation. A number of reviews are available discussing the use of CZE for speciation analysis of metals in different oxidation state, organometallic compounds, and metal complexes with different organic or inorganic ligands. In these applications, the proper selection of operational electrolytes to control acid–base and complex formation equilibria is the most important in controlling the effective electrophoretic mobilities of the analytes. Such applications are especially useful for the determination of transition metals, heavy metals and rare earth elements.

In addition to cations, CZE has also been used extensively for the separation and speciation of inorganic anions of arsenic, selenium, phosphorus, sulfur, halogen and phosphorus compounds. The mechanisms of anion separation by CE were reviewed by Kaniasky et al. and Haddad et al. Comparison between CE and RPLC techniques for metal speciations was reviewed by Timerbaev et al. The application of CE for the separation of inorganic metals and organometallic species in environmental samples including air particulates, soils and water samples was discussed in several recent reviews. The main emphasis of these reviews was placed on the discussion of matrix effects in complex environmental samples; and the different approaches one can take to minimize such matrix interference.

For the separation of organometallic or uncharged organic or biological molecules, MEKC (micellar electrokinetic chromatography) is the other CE technique commonly used. A recent review on the use of micelles as a separation media in both HPLC and CE applications was given by Khaledi. The set-up of the apparatus in MEKC is the same as those of CZE. The chief advantage of MEKC is that both neutral and charged compounds can be separated. Terabe et al. first reported the use of micelles in buffer solutions for CE in 1984. The charged micelles are incorporated in the buffer solution to act as a pseudo-stationary phase. The separation of the analytes is based on the differences in their partition coefficients between the buffer solution and the micelles. Such differences result in the separation of species, which by themselves would have the same electrophoretic mobilities, because of the electrophoretic migration of the micelles along the capillary. Furthermore, with the inclusion of suitable additives in the buffer, unique separation or selectivity may be exploited in MEKC.

MEKC has found wide applications for the separation of metal binding proteins, peptides or porphyrins. For the separation of these biopolymers, conditioning or shielding of the fused silica capillary wall is often necessary in order to avoid undesirable wall interactions of the analytes. Two approaches can be taken. The first is to apply dynamic coatings, with deactivator compounds added in the solution to continuously condition the capillary during separation. Alternatively, a permanently coated or organic polymeric capillaries can be used to replace the fused silica capillary commonly used.

The application of CE for speciation studies started to grow rapidly in the early 1990s. Most of these studies used on-line spectrophotometric or fluorescence detectors. Limited by detection sensitivity, this earlier work involved primarily the analysis of standard solutions or samples with higher metal concentrations. Table 1 lists selectively some of these reports to illustrate the range of application of CE techniques. The primary CE modes used in these studies were CZE and MEKC. All the listed studies were based on CE with UV/VIS detectors except the one by Schlegel, in which conductivity detector was used. The operating conditions, buffer systems used for each of these studies are included in the table along with sample and analysts information. The versatility of CE separation can be seen from its wide applicability in systems consisting of a variety of metals, anions and organometallic species in different types of sample matrices. The capability of CE is further enhanced when it is coupled with sensitive and elemental specific detectors such as plasma-based atomic spectrometry or mass spectrometry (MS), as will be discussed in later sections.

3 OPTIMIZATION OF CAPILLARY ELECTROPHORESIS SEPARATION

To achieve high efficiency in CE separation requires the careful control and systematic optimization of the various operating parameters in the system. The injection mode, pH control of the buffer solution, stability of the applied voltage, conductivity and electric current of the buffer system are all important factors contributing to the resolution and reproducibility of the separation.

The type of injection and injection duration are important in CE as it may bias the results and lead to poor separation and irreproducibility of migration times. The two basic sample injection techniques in CE are hydrodynamic injection and electrokinetic injection. The former is to introduce the sample by hydrodynamic flow through hydraulic pressure, while the latter is by
electrophoretic flow with applied d.c. potential. The volume of sample injected is a compromise between separation resolution and sensitivity requirement. Quite often in speciation studies, the concentration-based detection limits in CE have to be maximized through the injection of large sample volumes. However, increasing the injection volume risks the possibility of degradation in resolution because of overloading.

For large sample volumes, using electrokinetic injection will give a better resolution than hydrodynamic injection as the sample is continuously being separated during the entire injection period. Magnuson et al.\(^{41}\) reported enhanced sensitivity with detection limits in the ppt range for arsenic species of As (III) and As (V) by CE/ICPMS using electrokinetic injection. However, such injection often complicates the quantitation process as the amounts of individual analytes introduced during the sample injection period may vary depending on their respective electrophoretic mobilities and conductivities.\(^{40}\) Generally speaking, electrokinetic injection is a viable sample introduction technique which is more suitable for the analysis of samples requiring on-line preconcentration. But its precision and accuracy are strongly affected by experimental conditions and thus require tighter control compared with that of hydrodynamic injection.

Reproducible sample injection is crucial to obtain quantitative data in applying CE for speciation studies. Recently, a number of modified CE injection techniques based on flow-injection principles or automated devices have been developed.\(^{42–44}\) These injectors offer the opportunity for fully automated sample injection with high precision, and thus are preferred for applications involving CE hyphenated techniques for speciation studies.

The conditioning of the surface of the capillary is also important in achieving reproducible CE separation. The pH of the buffer system has a direct impact on the EOF because buffer pH affects the charge of the inner capillary tube surface. This is because the degree of protonation of the silanol groups increases with decreasing pH. Phosphate or other anions commonly used in buffer systems can also reduce EOF through the conversion of acidic silanols on surface to more easily protonated silica–phosphate complexes.\(^{45}\) Preconditioning of the capillary is therefore important to control the equilibrium of the surface charge.\(^{45,46}\) The use of CZE for the separation of arsenic species of As (III), As (V), MMA, DMA and arsenic acid (ANA) was found to depend significantly on capillary preconditioning and pH.\(^{47–49}\)

The separation efficiency of CE is related greatly to pH and the choice of buffer because they affect the electrophoretic mobility and separation efficiency of the analytes. During separation, charged species migrate in the capillary under the influence of an applied electric field. Ideally, the buffer should not interact chemically with the species of interest, maintain the pH and minimize ion loss. The choice of buffer often involves trade-offs between separation efficiency and peak resolution. In cation analysis, for example, cations with a high charge will be more easily trapped in the electrical double layer than cations with smaller charge. Thus, using a buffer containing a cation with a high charge will reduce analyte cation sample loss caused by trapping in the double layer. On the other hand, the higher charged ions are likely to interact with anionic ligands in the buffer, which affects resolution. The pH of the buffer should also be optimized since selectivity and resolution may occur at different pH range, and thus the two parameters need to be investigated individually.

The choice of buffer and its concentration also determines the conductivity of the solution within the capillary.\(^{50}\) Conductivity of the sample analytes and electrolytes is a main concern because it will affect the electrophoretic resolution as well as the amount of heat generated in the capillary. When the conductivity of the sample approaches or exceeds that of the electrolytes in the buffer solution, CE resolution is degraded. Increasing the conductivity of the electrolyte solution leads to increased Joule heating which produces peak broadening. On the other hand, if the conductivity of electrolyte is too high, heating may be large enough to increase the temperature of the electrolyte, and produces radial temperature gradients in the capillary. Consequently, convection currents will lead to mixing and the degradation of resolution. If the conductivity is too low, the voltage gradient in the injected sample plug and nearby analyst zone in the capillary will always be smaller than the voltage gradient in the electrolyte solution. As a result, electrophoresis peaks will also be distorted. It is generally recommended that the concentration of the electrolysts should be at least 1000 times the concentration of sample.

Applied voltage is another factor affecting CE separation. As the applied voltage is increased, the separation time is reduced. However, such increase causes an increase in electric current, resulting in Joule heating in the capillary. Consequently, the EOF and electrophoretic mobility of the analytes will also be affected. Thus, while high electric field often improve resolution and efficiency, the effects of Joule heating essentially sets the limit on such increase in real practice. For efficient separation, a stable and reliable electrical current along the capillary is necessary. In addition, the capillary should also be cooled actively during analysis to prevent local heating.
4 DETECTION SYSTEMS FOR CAPILLARY ELECTROPHORESIS

As the total sample intake by CE analysis is extremely low (5–100 nanoliter range), the concentration-based sensitivity of the detection system must be sufficiently high in order to be applicable in speciation analysis. The development of highly sensitive and selective detectors for CE has always been a subject of intense interest. Until today, ultraviolet and fluorescence detectors are the most commonly used ones for CE in speciation analysis. As was shown in Table 1, the detection limits of these detectors are generally in the order of 10⁻⁵ to 10⁻⁶ M range. Such sensitivity is not sufficient for the speciation analysis of trace quantities of analytes often faced in environmental samples. Other detection techniques such as MS, laser-induced-fluorescence, amperometry and conductivity have all been successfully applied as CE detectors with high sensitivity. However, these detectors lack the needed ‘elemental specificity’ to selectively detect the specific elemental species of interest in the presence of complex matrix interference.

As was stated earlier, the use of atomic spectrometry as an elemental specific detector in hyphenated techniques has been a popular approach in speciation analysis. Such detection may be single element in nature, e.g., atomic absorption spectroscopy (AAS), or multi-element, e.g., inductively coupled plasma optical emission spectroscopy (ICP-OES). The interface of chromatography with these detection devices is relatively straightforward due to the continuous flow characteristics and the compatible flow rates (mL min⁻¹ range) of the two partner devices. The early interface problems in these systems have now been mostly alleviated. Most of these interface systems such as high-performance liquid chromatography/inductively coupled plasma atomic emission spectroscopy (HPLC/ICP-AES) or gas chromatography/microwave induced plasma (GC/MIP) currently in use are relatively cheap and easy to construct, and can be readily constructed and demounted when not in use. The instrumental design and their applications in speciation analysis have been the subject of many reviews as was given in several articles included in the earlier references.

Before the wide availability of ICPMS, inductively coupled plasma atomic emission spectroscopy (ICP-AES) was the most popular detection systems used in hyphenated CE techniques. Olesik et al. was the first to report the application of CE/ICP-ES for elemental speciation of chromium and iron. The system was shown to be a viable technique for the rapid analysis of free ions of different charge states and organometallic species with sensitivities in the low ppb range. A similar system developed by Lu et al. was applied successfully for the speciation of Cu²⁺, Cu(EDTA)²⁻, and Cr³⁺ and Cr₂O₇²⁻ with sensitivities also in the ppb range. These and other earlier studies provided valuable information on the design of the interface and nebulizer to couple CE with the plasma systems. On the other hand, they also demonstrated clearly that further improvement in detection sensitivity is needed before hyphenated CE techniques can be utilized effectively for routine speciation analysis of real world samples.

ICPMS represents the newest generation of multi-elemental detection instrument. The state-of-the-art of the instrument can be found in many reviews including the more recent ones by Caruso et al. Compared to ICP-OES, ICPMS is 10–1000 times more sensitive, and offers simpler spectral interpretation with less interference. The analytical capability of MS to monitor ionic species from ICP has been well known since the mid-1980s by the work of Houk et al. Different versions of the instruments are now available commercially. In these instruments, the plasma torch is in a horizontal position under normal pressure. An interface cone is placed between the plasma source and the mass spectrometer. The ions produced in the ICP are transported into the MS through a small hole in the cone through a differentially pumped interface linked to a quadruple spectrometer. Quadruple MS are the most commonly used MS instrument as it is more compact, less expensive and more rugged than magnetic sector MS. The quadruple MS covers a mass range of 3 to 300, with unit mass resolution, and has a dynamic range of 6 orders of magnitude. Over 90% of the elements in the periodic table can be determined by ICPMS with detection limits in the sub-ppb range for most elements. The spectra so produced, which consist of a simple series of isotope peaks, are much simpler compared with conventional ICP emission spectra. These spectra can be used for quantitative measurement based on calibration curves, often with an internal standard. The fast scan rate and peak jumping routines of the quadruple MS result in an essentially simultaneous multi-element detection when it is interfaced on-line to different sample introduction systems.

ICPMS is an unique technique to discriminate between the masses of the different isotopes of an element where more than one stable isotope occurs. Consequently an enriched isotope that normally is present in relatively low abundance can be used as a tracer in metabolic studies to compare to a reference whose abundance is constant. Another major advantage is the application of isotope dilution analysis. Isotope ratio for two selected isotopes of an element of interest is measured in a solution after the addition of a known quantity of a spike that contains enrichment of one of the isotopes,
permitting calculation of the original concentration of the element. The use of isotope dilution saves the time required to obtain calibration graphs and compensates for matrix effects as was illustrated in the recent articles by Heumann et al.\textsuperscript{61,62} Using ICPMS coupled with SEC (size exclusion chromatography), these authors were able to determine the extent of complexation of Cu, Mo and Fe with different fractions of dissolved organic materials or humic substances in aqueous samples. The speciation of iodine compounds of iodate, iodide and organoiodine in fresh and seawaters were also successfully accomplished by the coupling of ICPMS with reversed-phase HPLC. The sensitivities of ICPMS detection for these species were down to the pg mL\textsuperscript{-1} range.

Since the late 1980s, a variety of ICPMS based hyphenated techniques have been reported in the literature. Thompson and Houk\textsuperscript{63} first reported the use of plasma MS as detector for HPLC for the speciation of As and Se. The study demonstrated the superior capability of ICPMS for multi-element detection and isotope ratio analysis with high precision and accuracy. A variety of sample introduction devices have since been interfaced to ICPMS for speciation applications. Figure 1 gives a schematic representation of the basic components of ICPMS; and the wide variety of sample introduction or chromatographic separation techniques with which ICPMS has been successfully interfaced.

The coupling of CE and ICPMS provides an ideal tool for speciation analysis because it combines the high separation efficiency of CE with high elemental sensitivity and specificity of ICPMS. The analytical performance and instrumentation of the variety of ICPMS-based hyphenated technique can be found in some recent reviews.\textsuperscript{64} Table 2 outlines the major attributes of CE and ICPMS which make the coupling of the two an attractive approach in speciation studies.

When used as a stand-alone instrument, ICPMS can generally use the same or closely similar sample introduction techniques that had been developed for the more well-established ICP-OES systems. Many high efficiency nebulizers have been developed to efficiently transport the liquid samples or chromatographic eluent to the...
plasma in aerosol forms so that they can be effectively vaporized, atomized, ionized or excited. However, different sets of problems occur when these interfaces are applied to CE. In the following text, general considerations on the design of the interface will be introduced. Some of the successful interfaces reported in the literature along with their applications will be described. A summary of the different systems studied in these reports is given in Table 3. The types of metal compounds which have been speciated and the corresponding detection limits for each of these species are included in Table 3. Details of these systems will be discussed further in later text.

The technique of CE/ICPMS is still in the early stage of development and thus only limited numbers of papers with experimental details have been published so far. The information summarized in Table 3 is meant to give an overview of the status of development of the technique rather than an exhaustive literature review.

5.1 General Consideration in Interface Design

There are three main challenges in the design of an interface between CE and ICPMS. First, in CE/ICPMS, different from those of conventional CE set-up, the exit end of CE capillary is no longer placed inside a grounded buffer reservoir. Thus, one has to find an alternative way to complete the electric connection in order to apply the high voltage across the entire CE capillary. Second, to achieve high concentration-based sensitivity, the transport efficiency of the interface needs to be as high as possible because of the small volumes of samples introduced in CE (5–50 nL). Lastly, along with high transport efficiency, the interface should also be able to minimize electrophoretic band broadening caused by problems of dead volumes or flow incompatibilities. To solve these problems requires a substantial modification of the conventional nebulizer/spray-chamber designs

DIN, direct injection nebulizer; HG, hydride generation.
commonly used for sample introduction in atomic spectrometry. Using these conventional nebulizers, which are built to handle flow rate in the mL min⁻¹ range, would not only lower the sensitivity due to sample loss or dilution, but also degrade the electrophoretic peak shape because of dispersion in the laminar flow of the conduits.

Two general approaches have been taken to achieve proper electric connection of the CE capillary in CE/ICPMS. In the first approach, the electric connection to the capillary was made by conducting silver paint on the outside of the capillary. The grounded cathode end is then placed directly into the nebulizer for sample transport to the plasma. The second approach is to mix an electrically conductive sheath buffer flow to combine with the CE flow at the tip of the CE capillary before entering the nebulizer. The sheath flow serves two purposes. Besides serving as an electrical connection to the cathode end of the separation capillary, it also serves as a make-up flow to match the liquid flow requirement of the nebulizer. All the connections and tubings used in these interfaces are micro-volume connectors in order to minimize the dead volume. The operating conditions such as buffer composition, flow compatibility and nebulizer gas flow rate also have to be carefully optimized to obtain satisfactory performance. Interfaces based on the use of sheath flow design have been found to give minimum band broadening with aerosol transport efficiency in the range of 20–80%, depending on the total liquid flow rate delivered to the nebulizer.

Many different new designs of nebulizers for CE interface have been reported in the literature, and these include DIN without the use of a spray chamber, and low-flow versions of concentric nebulizers based on Meinhard concentric nebulizer design coupled with low volume spray chambers. The transport efficiency in general is close to 100% for the direct injection techniques, and better than 50% for the low-flow nebulizers.

Although both CE and ICPMS are now well established techniques by themselves, the coupling of CE with ICPMS is relatively new and interface designs are still being developed and improved. Up to the present, there has not yet been a fully commercialized CE/ICPMS in the market which is of universal utility to all types of analytes of interest. Nevertheless, the use of direct injection nebulization and low-flow nebulizers appears to hold the best potential for routine applications.

### 5.2 Glass Concentric Nebulizer

Olesik first described the application of CE/ICP-OES/MS for elemental speciation. A commercial Mainhard concentric nebulizer was modified to couple CE capillary to ICP. The electrophoresis capillary was fitted into the inner tube of the nebulizer. The outside 4–5 cm of the capillary was coated with silver paint, which serves as an electric connection between the solution at the tip of the capillary and the ground. Under some conditions, contamination of the capillary effluent by Ag was observed, especially when ligands capable of complexing strongly with Ag were present in the buffer solution. A close to zero liquid dead volume and up to 100% sample transfer efficiency was obtained with the interface.

Using this interface, a series of Cr and Fe compounds were separated and detected using CE/ICP-OES. Satisfactory electrophorograms of a series of separations of tin (Sn⁴⁺ and Sn²⁺), strontium (Sr²⁺), arsenic (As (III) and As (V)) and chromium (Cr (III) and Cr (VI)) species presented each at 1 ppm concentration was reported. The separation of free ions from metal ligand complexes such as the mixture of Cu²⁺, Cu(EDTA)²⁻ was also accomplished. The detection limit for Sr using CE/ICP-OES with an injection volume of 0.14 µL was 0.3 ppb, compared with 0.03 ppb obtained with direct ICP-OES using conventional sample introduction techniques. The interface was also used to couple CE with ICPMS and the detection limits found in these coupled systems were in the range of 0.06–2 ppb for the elements investigated. Detection limits for Sr, Cr, As and Sn by CE/ICPMS were a factor of 6–200 times worse than that of direct ICPMS analysis using standard nebulizers and spray chambers. These initial studies suggested the promising potential of CE/ICPMS technique, but also the need for sensitivity improvement in order to be used for routine speciation analysis of real world samples.

Another version of Meinhard type nebulizer design was developed by Lu et al. The unique feature of this design is the variable positioning of the capillary in the concentric nebulizer. The CE capillary was inserted into the central glass tube of the nebulizer, about 2 cm away from the tip. Another silica capillary was also inserted coaxially into the central tube around the CE capillary. The maximum distance between the end of the CE capillary and the outer tube was 18 mm. A coaxial liquid sheath using 10 mmol L⁻¹ NaCl solution was supplied through the outer capillary used to complete the electric circuit of CE. The signal was found to decrease as the make-up sheath flow increases because of sample dilution by the make-up flow.

The system was used for the analysis of metal binding proteins, metallothionein and ferritin. The effect of CE capillary positioning on separation resolution was studied. Because of suction induced by the nebulizer, the farther the capillary was placed inside the nebulizer, the poorer was the resolution. The problem can be overcome by supplying negative pressure to the sample vial, but a compromise has to be made between resolution and signal intensity, which is affected by pressure applications. The detection limits reported were 2.5 µg of Fe g⁻¹ and...
0.055 µg of $^{114}$Cd g$^{-1}$. The absolute detection limits for 73.6 nL sample injection were 184 fg of $^{57}$Fe and 4 fg of $^{114}$Cd.

Mei et al.$^{(69)}$ reported a new version of the modified concentric nebulizer interface. The interface used a simple Y quartz tube. The first arm was connected with the outer end of the CE capillary. The second arm was connected with the auxiliary capillary used to draw up the make-up flow. The other end of the auxiliary tubing was dipped into the 0.05 M HNO$_3$ solution. The third arm was connected directly to the sampling tube of the nebulizer. The solutions were individually sucked up into their respective capillaries by self-aspiration and then mixed in the junction before being aspirated into the nebulizer. While the make-up solution was contacting with the ground of the d.c. supply, the buffer electrode solution was connected to the negative polarity of the d.c. supply. The negative high voltage was used to form an opposite EOF against the self-aspirating flow. Because the interface was placed outside and independent of the nebulizer, it is more flexible and could be easily connected to various types of nebulizers. High efficiency separation of Cu$^{2+}$, Cu(EDTA)$_2$$^{2-}$, and Cr$^{3+}$ and Cr$_2$O$_7^{2-}$ pairs was observed.

5.3 Direct Injection Nebulizer

DIN is a micro-concentric pneumatic nebulizer without the use of a spray chamber. Instead, the liquid sample is nebulized directly into the central channel of the plasma torch.$^{(72)}$ A commercial DIN unit is now available in the market. DIN has been used widely as an interface for micro-bore HPLC/ICPMS systems because of its high transport efficiency, low dead volume, and flow compatibility with the chromatographic systems.

Liu and coworkers$^{(73)}$ used a Microneb 2000 DIN nebulizer to interface CE with ICPMS. The CE capillary is inserted concentrically inside the fused-silica DIN sample introduction capillary. A liquid make-up flow in the DIN sample introduction capillary around the CE capillary was inserted concentrically inside the fused-silica DIN sample introduction capillary. The design has an extremely small internal volume of $<2$ µL min$^{-1}$ and can accommodate low rate in the range of 10–100 µL min$^{-1}$. Besides serving as the electric contact, the make-up flow design in DIN is also used to ensure that the DIN system could be operated independently of the CE system, and thus independently of the EOF generated by the electrophoresis process. This is advantageous because it allows the use of different buffers and applied voltages to optimize separation.

It was found that the DIN interface did not cause any noticeable suction and back pressure problems during CE analysis. Baseline separation of Li$^+$, K$^+$, Sr$^{2+}$ and Ti$^+$ was achieved in less than 210 s. The detection limits ranged from 7 pg mL$^{-1}$ for Ti$^+$ and 1000 pg mL$^{-1}$ for K$^+$. Satisfactory results were also reported for the speciation analysis of Se and As.

5.4 Ultrasonic Nebulizer

Ultrasonic nebulizers (USN) are used widely in ICPOES to improve transport efficiency and detection capability for elemental analysis. Its improvement over conventional pneumatic nebulizer systems is the dense aerosol and smaller droplet produced, and the resulting 3–8 times improvement in detection limits.$^{(74)}$

In a series of studies, Lu and Barnes$^{(67)}$ have made a systematic comparison of the efficiency and resolution between USN and conventional concentric nebulizers as an interface in CE/ICPMS. A commercial pneumatic-based USN was used in the study. The USN interface was found to provide considerable improvement in separation resolution and better signal sensitivity. It also showed lower sensitivity to mechanical parameters. The systems were used for the separation of metallothioneins. The signal intensity of the USN system showed an improvement of 3.6–8.4 fold compared to those with the concentric nebulizer interface. The gain in sensitivity, however, was compromised by the high background noise. Caruso et al.$^{(75)}$ has recently improved the USN interface design which showed noticeable improvement in resolution and signal/noise ratio.

5.5 Oscillating Capillary Nebulizer

Caruso et al.$^{(76)}$ recently reported the use of a pneumatic-based Oscillating Capillary Nebulizer (OCN) as an interface for CE/ICPMS. One attractive feature of the interface is its compatibility with a wide range of flow rates from 1 µL min$^{-1}$ to 2 mL min$^{-1}$. The transport efficiency was close to 100% under low flow rate conditions. In OCN, the aerosol was generated by both the flow of the nebulizer gas and the induced oscillation of the transport tubes. The concerted action enhanced the breakup of liquid samples into small droplets. The design used by Caruso is a modified version of the original model. The original OCN was constructed from two concentrically mounted flexible fused-silica tubes used each for the liquid and nebulizer gas flows. In the modified version, a three tube system was used and the additional tube was installed to accommodate a makeup buffer flow for ground connection.

Detection limits in the low ppbs were reported for the analysis of both inorganic cations and anions using the system. However, noticeable broadening and tailing of the peaks were also observed. It was suggested that both the turbulence in the spray chamber and the action of nebulizer suction could be responsible for the problems observed.
5.6 Hydride Generation

HG provides a different approach to interface CE with ICPMS.\textsuperscript{71,77} It circumvents some of the problems in nebulizer-based interfaces in which the CE buffer often causes the build up of deposits on the sampling interface, and thus influences the long term stability of the system. On the other hand, the gaseous hydride can be nearly quantitatively introduced into the plasma without the problem of high dissolved solids commonly associated with CE buffers. The common problem of chloride interference (\textit{m/z} of 75) in HG systems can be eliminated by using a microporous membrane as the separator.

The HG system is particularly useful for the specification of hydride-forming species such as As, as was demonstrated in the work by Mathew et al.\textsuperscript{77} In their system, the CE unit is interfaced to a microporous membrane as the gas–liquid separator before ICPMS detection. As (III), As (V), DMA and MMA can be speciated in real water systems in less than 5 min.

Magnuson et al. described the use of hydrodynamic modified EOF CE (HMEOF) with HG and ICPMS detection for As speciation.\textsuperscript{41,71} A microporous PTFE tube was used as a gas–liquid separator. In HMEOF, the EOF in CE was modified by hydrodynamic pressure opposite to the direction of the EOF. HMEOF permits the injection of increased quantities of analytes for sensitivity enhancement. Because of the low flow from the capillary, a makeup buffer flow was used. The capillary ground was also completed through this makeup flow. The CE/HG/ICPMS system was able to speciate arsenic species in real water samples with detection limits down to parts per trillions for As (III) and As (V).

An interesting alternative to the conventional hydride generation techniques recently reported is the movable reduction bed hydride generation system (MRBHG) developed by Wang and co-workers.\textsuperscript{49,78} They have used the MRBHG as an interface in both ICPOES and ICPMS systems. The unique feature of the MRBHG device is its capability to carry out HG reactions in a liquid/solid system at microliter sample volumes, and without the use of gas–liquid separators or the addition of acid solutions to the sample. Instead, the hydride forming reactions take place on the surface of a moving tape which has been precoated with a mixture of dry NaBH\textsubscript{4} and solid tartaric acid powders at appropriate ratios. During a CE run, the eluent from the capillary, combined with a makeup flow, is made to drip continuously onto the tape surface. Hydride forming reactions occur upon the contact of the aqueous eluent from CE with the reagents on the surface. The ‘reduction-bed’ on the tape surface is continuously refreshed by the constant movement of the tape during a run.

The construction of the system is shown in Figure 2. In the set-up, the reagent-coated rolling tape is situated inside a sealed reaction chamber. The tape is made to move at a specified rate by turning the two tape rollers that are placed in a sealed organic glass cassette. The tape then crosses the two holes on the stopper into and out of a reaction chamber. The hydrides produced in the chamber are swept into the ICP torch by argon carrier gas.

Compared with conventional HG techniques, MRBHG provides some unique advantages. The major ones include: (1) its ability to handle very small sample sizes down to the \textmu L volumes, (2) it suffers less chemical interference from other co-existing hydride forming elements in the sample matrix, (3) its efficiency in HG is insensitive to solution pH over a wide pH range, (4) its general applicability to all hydride forming elements of different valence state and chemical forms, and finally (5) its low cost of operation since no complicated apparatus is needed. The advantage of the system as a CE/ICP interface is its low dead volume because of the elimination of the use of complex plumbing and the gas–liquid separator.

The above authors have applied the MRBHG interface in both CE/ICPOES and CE/ICPMS systems for the speciation of four arsenic species including As (III), di-sodium methylarsonate, dimethylarsinic acid and As (V).
The detection limits reported for the optical emission spectroscopy (OES) system were in the range of $0.3\mu g mL^{-1}$.(78) Much lower detection limits were obtained in the ICPMS system, and the sensitivities observed for the same arsenic species were better than $10 ng mL^{-1}$.(49)

Cyanogen chloride (CNCl) (CAS 506-77-4) is a common disinfection by-product (DBP) formed in chloraminated waters. Cyanogen bromide (CNBr) (CAS 506-68-3), the brominated analog of CNCl, is formed in chloraminated or ozonated waters that are high in bromide. Both CNCl and CNBr are labile in drinking water. They undergo degradation reactions at high pHs or in the presence of free chlorine or sulfite. Because of its potential health effects, CNCl was included in the United States Environmental Protection Agency (USEPA) Information Collection Rule (ICR). Aqueous standards for CNCl are generally prepared with pure CNCl gas. They can also be prepared with chlorinated or chloraminated cyanide (CN\(^{-}\)) solutions. Aqueous standards for CNBr are prepared with commercially available CNBr. For sample preservation, ascorbic acid is commonly used to quench the residual chlorine or chloramines. Acid is often added to lower the pH to prevent possible hydrolysis degradation. There are three methods for analyzing CNCl and CNBr in drinking water samples: purge-and-trap gas chromatography/mass spectrometry (PT GC/MS), headspace gas chromatography/electron-capture detection (GC/ECD), and micro liquid–liquid extraction gas chromatography/electron-capture detection (LLE GC/ECD). All three methods are capable of analyzing microgram per liter levels of CNCl and CNBr in drinking water, and all three give similar method performance, including accuracy, precision, spiking recovery, and method detection limit. The PT GC/MS method is a modification of the USEPA Method 524.2, which requires the use of specialized instrumentation. Because of CNBr’s low vapor pressure and high water solubility, the analysis of CNBr also requires a heated purge. Headspace GC/ECD method is a relatively simple and rapid analytical method. As the samples are prepared individually, the method requires a full-time analyst to prepare and inject each sample. However, this analytical procedure can be automated using a commercially available headspace autosampler. In general, micro LLE GC/ECD is a well developed and common procedure for DBP analysis. The micro LLE GC/ECD method, originally developed for CNBr analysis, has been further developed for both CNCl and CNBr analysis in drinking water. The sample injection generally is automated with a common gas chromatography (GC) autosampler.

1 INTRODUCTION

Since chloroform was first reported in chlorinated drinking waters in the 1970s, many DBPs have been identified, including trihalomethanes (THMs), haloacetic acids (HAAs), and other miscellaneous DBPs. To address the concern over the presence of DBPs in finished drinking waters, the USEPA promulgated two DBP regulations, the ICR\(^1\) and the Disinfectants and Disinfection Byproducts (D-DBP) Rule.\(^2\) New maximum contaminant levels (MCLs) have been set by the USEPA for total THMs and five HAAs under the D-DBP rule.\(^2\) Chloramines, which are inexpensive and persistent disinfectants, have been used by many water utilities to control the formation of DBPs. A 1989–90 survey indicated that 20% of the utilities reported using chloramines as part of their THM
minimization program. The percentage could be significantly increased as a result of the D-DBP regulation.

CNCl is a product of the reaction between chloramines and natural organic matter (such as fulvic acid or amino acids). In a survey of 35 water utilities reported by Krasner et al., CNCl was detected typically in chloraminated water but not in waters containing a free chlorine residual. The concentration of CNCl in chloraminated waters ranged from 1 to 12 µg L\(^{-1}\). CNBr, the brominated analog of CNCl, is formed in chloraminated or ozonated waters that are high in bromide. In a water containing 0.11–0.39 mg L\(^{-1}\) of bromide, 1.5–3.7 µg L\(^{-1}\) of CNBr was reported, whereas concentrations of CNCl were between 9 and 18 µg L\(^{-1}\). In another study, increasing bromide levels increased the concentration of CNBr and decreased the formation of CNCl but had little effect on the sum of the molar concentration of CNCl and CNBr, as shown in Figure 1. At bromide levels of 0.3 mg L\(^{-1}\) or higher, CNBr became the dominant form.

Both CNCl and CNBr are labile in drinking waters and undergo degradation reactions at high pHs, or in the presence of free chlorine or sulfite. The degradation rates were well studied by two research groups. The two studies reported similar CNCl degradation rates at various experimental conditions. At high pHs, both CNCl and CNBr undergo hydrolysis degradation to form cyanate. At pH 10, the half-life of CNCl has been estimated at 43 min and at 21 min. The half-life of CNBr was reported as 34 min at pH 10. The hydrolysis degradation may significantly affect the stability of CNCl and CNBr in distribution systems or during sample storage. In the presence of free chlorine, CNCl undergoes much faster degradation reactions. At pH 7 and a free chlorine concentration of 0.5 mg L\(^{-1}\), the half-life of CNCl was 60 min. At pH 9.2 and a free chlorine concentration of 5.68 mg L\(^{-1}\), the half-life of CNCl was 1.9 min. These results may well explain why high levels of CNCl or CNBr are rarely found in waters containing a free chlorine residual. In the presence of sulfite, CNCl undergoes degradation reactions. In the presence of 25 µM sulfite and at pH 7, the half-life of CNCl was 76 min, whereas CNBr decomposed completely in 5 min. In another study, the half-life of CNCl was 22 min at pH 7 and in the presence of 78.9 µM sulfite. Therefore, there is a need to be extremely cautious when using sulfite to quench residual chlorine or other oxidants.

Because of its hazardous nature and possible health effects, CNCl was listed in the USEPA’s first drinking water priority list. CCl was also included in the USEPA ICR which required water utilities using chloramines to monitor CNCl in their finished water. CNCl may also become regulated under the USEPA Stage 2 D-DBP regulation. Because there are greater health concerns over brominated DBPs, CNBr, a brominated DBP in ozonated and chloraminated waters that are high in bromide, may also be included in future regulations.

2 STANDARDS PREPARATION

Accurate and stable standards are essential for quantitative analyses of environmental contaminants. Standards are needed to prepare calibration curves and determine other method performance parameters. For CNBr standards, the pure chemical can be purchased commercially (e.g. Aldrich Chemical Company, Inc., Milwaukee, WI, USA). For CNCl, pure CNCl gas (Island Pyrochemical Industries, Mineola, NY, USA) or CNCl diluted standards (Protocol Analytical Supplies, Inc., Middlesex, NJ, USA) may be purchased. The instability of CNCl diluted stocks and the hazardous nature and high cost of pure CNCl gas, however, have significantly limited the capability of many laboratories to analyze CNCl samples. Under the ICR, as the USEPA could not provide performance evaluation samples or calibration standards, no laboratory was approved for CNCl analysis except the USEPA laboratory. All participating water utilities were requested to send CNCl samples to the USEPA laboratory for analysis.

2.1 Preparation of CNCl and CNBr Standards with Neat Chemicals

CNBr primary methanolic standards are prepared gravimetrically. Using an analytical balance, weigh an exact mass of pure CNBr into 10–50 mL of methanol. CNCl
primary methanolic standards are also prepared gravimetrically. Because of its low boiling point, CNCl is in gas form at room temperature. Prepare CNCl solution as follows.\(^{17,8}\) Using a glass syringe, equipped with a luer lock adapter and a two-way syringe valve, transfer approximately 15 mL of the pure CNCl to a preweighed 40-mL septum-capped vial containing 10 mL of methanol. Weigh the vial again and use the weight difference to determine the exact amount of CNCl added. This primary standard yields a concentration of approximately 2500 mg L\(^{-1}\). CNCl primary standards can also be prepared by exhausting 10–50 mL of CNCl gas over 10 mL methanol in a volumetric flask.\(^{13}\)

Secondary or tertiary standard solutions are diluted in methanol from the primary stock. Store both CNBr and CNCl methanolic standard solutions in a \(-10^\circ C\) freezer. These standards are stable for 4–5 weeks.\(^{13}\) The stability of standards can be improved by using different solvents (e.g. acetone or acetonitrile), as suggested by Protocol Analytical Supplies, Inc. Aqueous standards are prepared by diluting the secondary or tertiary standard with reagent water. Because of the hydrolysis degradation of both CNCl and CNBr, aqueous solutions should be freshly prepared. Aqueous standards should be used to prepare the calibration curves.

CNCl is a highly toxic and volatile chemical. Because of its hazardous nature, CNCl gas is very expensive to purchase, transport and dispose of. The price of a bottle of gaseous CNCl ranges from US $2200 for 0.7 lb to US $700 for 0.5 lb.\(^{14}\) Be extremely cautious when using CNCl gas. Commercial CNCl gas may contain a high percentage of impurities (e.g. hydrogen cyanide) or stabilizers (e.g. tetrasodium pyrophosphate) which may significantly affect the accuracy of the analytical results.

2.2 In Situ Synthesis of CNCl Standards

In situ synthesis of CNCl standards was reported by Wu et al.\(^{14}\) The method consists of quantitatively converting cyanide to CNCl in the presence of excess free chlorine or chloramine T (sodium N-chloro-p-toluene sulfonamide). As the CNCl synthesized standards are aqueous standards, there is no need to prepare primary, secondary or tertiary methanolic standard solutions. All chemicals used for CNCl synthesis should be reagent grade or better.

First, using an analytical balance, weigh and dissolve 0.212 g of KCN (CAS 151-50-8) into 100 mL of reagent water.\(^{14}\) This cyanide stock solution is equivalent to 847 mg L\(^{-1}\) of CN\(^-\) or 2000 mg L\(^{-1}\) of CNCl solution. Take 1 mL of the cyanide stock solution and dilute it into 1000 mL using reagent water. The diluted cyanide solution is the primary cyanide solution. Take 5 mL of primary cyanide solution and dilute it with approximately 30 mL reagent water. Then add 4 mL of phosphate buffer (0.5 M), followed by the addition of NaOCl solution at a chlorine dose between 0.5 and 5 mg L\(^{-1}\). Alternatively, 2 mL of chloramine T solution may be used instead of NaOCl solution. Immediately bring the mixture to 50 mL with reagent water. After exactly 2 min of reaction, add 25 mg of ascorbic acid to quench residual chlorine. After 30–40 s reaction, this primary CNCl standard, with a CNCl concentration of 200 µg L\(^{-1}\), is ready for further dilution to various calibration standard concentrations. Cap the calibration standards headspace-free and store them at 4 ºC in the dark.

The free chlorine-generated CNCl was stable for at least 2 days, and 1 h for chloramine T-generated CNCl, as shown in Figure 2.\(^{14}\) The free chlorine-generated CNCl could be used as a calibration standard or a quality control check sample without repeated synthesis. Because of its instability, chloramine T-generated CNCl needs to be freshly synthesized; however, the synthesis is easily done in less than 10 min.

![Figure 2](image-url)

Figure 2 Stability tests of synthesized standards: (a) generated with hypochlorite; (b) generated with chloramine T. [Reprinted from Water Research, Vol. 32, Wu, Chadik and Schmidt, ‘An In Situ Synthesis of Cyanogen Chloride as a Safe and Economical Aqueous Standard’, 2867, Copyright (1998), with permission from Elsevier Science.]
As reported by Wu et al., the synthesized CNCl standards are comparable with standards prepared with pure CNCl gas. Microgram quantities of synthesized CNCl are easily disposed of by conversion to innocuous cyanate by simply raising the pH. The in situ synthetic procedure is a safe and economical way to prepare CNCl standards. This procedure is especially useful for laboratories in areas where CNCl is difficult to acquire.

2.3 Commercially Prepared Stock Standards

Commercial CNCl standards at 100, 200, 1000, 2000, or 5000 µg L⁻¹ in acetonitrile are available from Protocol Analytical Supplies, Inc. CNCl standards in methanol or acetone can also be obtained from them upon special request. The standards in methanol are least stable and those in acetonitrile are most stable. Sealed ampules and solvent-diluted standards should be stored at −10°C until use.

3 SAMPLE COLLECTION, PRESERVATION, AND STORAGE

3.1 Sample Collection

It is recommended that CNCl and CNBr samples are collected in duplicate or triplicate in nominal 40-mL vials with poly(tetrafluoroethylene) (PTFE)-faced septa and threaded polypropylene caps. If the sample is to be taken from a tap, flush the line for approximately 5 min to allow the water temperature to stabilize and to avoid sampling stagnant water. Adjust the flow to a stream that is gentle enough to prevent aeration of the sample and fill the vials. If a preservative is present do not rinse the bottles before filling or allow them to overflow. Seal the sample vials headspace free.

3.2 Sample Preservation

CNCl and CNBr degrade at high pHs or in the presence of free chlorine residual. Formation of CNCl and CNBr may continue if both natural organic matter and a combined chlorine residual are present. Dechlorination and pH adjustment are recommended in combination with cold storage to preserve the samples.

3.2.1 Dechlorination

Any free or combined chlorine residual must be quenched. Approximately 0.1 mL of 25 mg mL⁻¹ freshly prepared ascorbic acid solution per 40-mL sample is sufficient to remove a chlorine residual of 1 mg L⁻¹. Add an appropriate amount of ascorbic acid, but avoiding an excess which could degrade CNCl and CNBr. Be extremely cautious when using sulfite to quench free or combined chlorine residual. Both CNCl and CNBr degrade rapidly in the presence of sulfite. Trace amounts of sulfite carried over into the purge-and-trap (PT) or GC (e.g. injector or column) system may also significantly impair instrumental sensitivity for CNBr. Ammonium chloride is not a true chlorine quenching reagent. It converts free chlorine to combined chlorine. Addition of ammonium chloride may not stop the continuous formation of CNCl and CNBr in water samples.

3.2.2 pH Adjustment

To prevent the possible hydrolysis degradation of CNCl and CNBr, the pH of the samples must be lowered to 3.0–3.5. For typical drinking waters (i.e. not highly buffered and at pH 7–8), add approximately 0.2 mL of 1 M sulfuric acid to each 40-mL vial. Check the pH of unknown samples on an extra vial.

3.3 Sample Storage

Store samples iced or in a refrigerator at 4°C. Typical water samples, even with dechlorination, pH adjustment, and refrigeration, should be analyzed within 48 h for CNBr and within 2 weeks for CNCl. It is best to analyze samples for CNCl and CNBr as soon as possible after collection.

4 ANALYTICAL METHODS

4.1 Purge-and-trap Gas Chromatography/Mass Spectrometry

4.1.1 General Discussion

The PT technique permits introduction of a high analyte concentration into the GC or GC/MS without any accompanying liquid (water or solvent). A high concentration factor is achieved because the analyte from a 25-mL water sample is injected into the GC. Volatile analytes are stripped from the water sample by a stream of nonreactive gas (helium or nitrogen) and trapped on a sorbent (resin or activated carbon). Analytes are desorbed by rapid heating of the trap and are carried into the GC by the carrier gas for separation and detection. With narrow-bore GC columns, a cryo-trap is used to refocus the compounds and reduce peak width. The PT technique has been used for many years for the analysis of volatile organic compounds including solvents and aromatic gasoline components, such as in USEPA methods 524.2 and 503.1.

The PT GC/MS method for the analysis of CNCl was first developed by Flesch and Fair using USEPA method 524.2. The PT GC/MS method was the approved method used to collect occurrence data from
U.S. utilities using chloramine residuals under the ICR. Krasner et al. modified the method to include the analysis of CNBr in addition to CNCl.\(^5\) Because CNBr is less volatile than CNCl, the sample had to be heated to achieve effective transfer to the trap. Detection is by mass spectrometry (MS), with spectral identification and quantitation based on a single ion chromatogram.

4.1.2 Sample Preparation and Analysis

Commercial PT systems are available or a system can be built from a fritted gas washing bottle plumbed to a stainless steel trap with deactivated fused silica transfer lines to the GC/MS. First bring samples to room temperature. Pour the sample into a 25-mL gas-tight syringe, insert the plunger, adjust the volume to 25 mL and add fluorobenzene (CAS 462-06-6) internal standard to give a concentration of 0.5 \(\mu\)g L\(^{-1}\). Transfer the sample to the purge vessel and initiate the gas flow. Purge, trap, and desorption and GC/MS operating conditions are given in Table 1.\(^{13,16,17}\) After purging is complete, switch the gas flow to carry the analytes from the sorbent trap to the GC and heat the trap. Simultaneously, a short piece of deactivated fused silica precolumn is cooled with liquid nitrogen to refocus the analytes. Then ballistically heat the cryotrap to inject the sample onto the analytical GC column. The GC injector is not used. Hold the GC oven at \(-10^\circ\)C from the start of sorbent trap desorption until the start of the GC temperature program at the end of the cryofocusing process.

Aqueous standards of CNCl and CNBr analyzed by the same method should be used to establish a calibration curve based on the ratio of the area of analyte divided by the area of the internal standard. The masses used for quantitation are 61 \(m/z\) for CNCl, 105 \(m/z\) for CNBr, and 96 \(m/z\) for the internal standard, fluorobenzene. Typical spectra for CNCl, CNBr, and fluorobenzene, are shown in Figure 3.

4.1.3 Discussion

Typical gas chromatograms of a PT analysis of CNCl and CNBr calibration standard are shown in Figure 4. The GC run time was less than 9 min. A typical calibration curve for CNCl over a concentration range of 0.2–20 \(\mu\)g L\(^{-1}\) was linear with an \(R^2\) value of 0.997, and for CNBr over

a concentration range of 0.5–20 μg L⁻¹ a quadratic fit with an $R^2$ value of 0.997. The method detection limits, based on seven replicate analyses, were 0.13 μg L⁻¹ for both CNCl and CNBr. However, the CNBr calibration curve does not pass through zero, indicating a threshold concentration. Therefore a minimum reporting limit of 0.5 μg L⁻¹ is used for CNBr. By analyzing 12 treated surface water samples spiked with 5 or 10 μg L⁻¹ cyanogen chloride and cyanogen bromide, the mean recovery was determined to be 96 ± 18% for CNCl and 88.5 ± 20.9% for CNBr.

The heated PT GC/MS method was the first method to analyze CNBr in drinking water and provided valuable information about its formation and biodegradation. A good transfer efficiency (25%) was achieved for CNBr. However, the heated PT method is difficult to run continuously because water vapor is carried over to the trapping system. When both CNBr and CNCl analyzes are required, headspace GC/ECD and micro LLE GC/ECD are more cost effective and precise methods. Ambient temperature PT GC/MS is an efficient method for the analysis of CNCl and can be run in conjunction with the determination of other volatile organic compounds. It also provides the advantage of mass-spectral compound identification and can eliminate interference from unresolved GC peaks.

4.2 Headspace Gas Chromatography/Electron-capture Detection

4.2.1 General Discussion

Headspace GC method is a common procedure for analyzing volatile organic compounds in aqueous samples. The analytical procedure includes headspace preparation and GC analysis. The headspace preparation involves transferring volatile substances from the liquid phase into the gas phase (or headspace). Increasing the interfacial area between the gas and liquid phases by shaking the samples increases the efficiency of mass transfer and reduces the time required for reaching the gas–liquid equilibrium. At equilibrium, the concentration of a substance in gas phase is proportional to its concentration in the liquid phase, according to Henry’s law. The concentration of the substance in the gas phase is analyzed by GC. The calibration curves are prepared by analyzing aqueous standards at various concentrations. As most of the volatile substances occur in water samples at microgram per liter levels, linear calibration curves are easily obtained.
The CNCl has a boiling point of 13.1 °C at 1 atm. At 20 °C, the Henry’s law constant was estimated as 0.9 atm L mol⁻¹. CNBr has a boiling point of 61–62 °C at 1 atm and a Henry’s law constant of 0.16 atm L mol⁻¹ at 20 °C. These properties indicate that CNCl and CNBr can be easily analyzed by headspace GC/ECD.

4.2.2 Sample Preparation and Analysis

Pour water samples into 40-mL vials without aeration and cap the vials headspace free with PTFE-faced septa and screw caps. Prior to headspace preparation, bring the water samples to ambient temperature (20 °C). An internal standard, 1,2-dibromopropane (CAS 78-75-1), may be added at this point to monitor method performance. The recommended concentration for the internal standard is 50 µg L⁻¹. A bare syringe needle and a syringe equipped with a stainless steel needle are needed to prepare the headspace. First, fill the syringe with 10 mL of nitrogen (99.999%). Force both needles through the septa on the sample vial. The tip of the bare needle should be placed close to the septa and the tip of the syringe needle should be placed in the middle of the sample vial. While keeping the sample vial upside down, gently depress the plunger on the nitrogen-containing syringe. The displaced sample volume is expelled through the bare needle. Remove the needles and vigorously shake the sample vial for 1 min by hand. After settling for 10–20 s, the gas phase is ready for sampling. Withdraw 400 µL of headspace sample using a 1 mL or 500 µL gastight syringe, and inject the headspace sample into the GC in the split mode.

A gas chromatograph equipped with a split/splitless injector and an electron capture detector (ECD) is required for CNCl and CNBr analysis. Typical GC operating conditions for headspace GC/ECD are shown in Table 2.

4.2.3 Discussion

Typical gas chromatograms obtained with headspace GC/ECD are shown in Figure 5. Both CNCl and CNBr are well separated. A small negative peak was observed just prior to the elution of CNCl. This caused a non-zero intercept in the calibration curves. This phenomenon was not observed by Sclimenti et al. The calibration curve for CNBr always passed through the origin.

The method detection limits were estimated to be 0.04 µg L⁻¹ for CNCl and 0.2 µg L⁻¹ for CNBr. By analyzing 11 fulvic acid solution samples (4 mg L⁻¹ dissolved organic carbon) spiked with 5 µg L⁻¹ CNCl and 10 µg L⁻¹ CNBr, the spiking recovery was determined.

had little impact on the analytical results.\(^{(8)}\) Adding supplemental salt at 100 g L\(^{-1}\) and/or increasing temperature beyond 25°C might improve the detection limit for both CNCl and CNBr. However, addition of such large amounts of any salt or heating samples at high temperature would present a new opportunity for contamination or sample degradation, especially for CNBr.

The headspace GC/ECD method is a simple and rapid method for analyzing CNCl and CNBr. The total time for headspace preparation and GC analysis is less than 12 min. Having analyzed more than 250 samples with this method,\(^{(8)}\) it was concluded that this method is rapid, simple, and robust.

4.3 Micro Liquid–Liquid Extraction Gas Chromatography/Electron-capture Detection

4.3.1 General Discussion

Liquid–liquid extraction (LLE) is a common concentration procedure for organic analysis. Traditionally a separatory funnel or a continuous extraction apparatus is used to facilitate the extraction of liter-size samples. Micro LLE uses a small volume of water sample and extraction solvent. Generally, the extraction is conducted in a 40-mL sample vial and there is no need to concentrate the extract. Addition of a salt (e.g. sodium sulfate) is used to increase the extraction efficiency and improve the separation of solvent and aqueous phases. This extraction technique has been used for analyzing many DBPs, including THMs (USEPA method 551.1), HAAs (USEPA Method 552.2 and Standard Method 6251), aldehydes (Standard Method 6252), and ketoacids\(^{(19–22)}\).

The micro LLE GC/ECD method was first developed for the analysis of CNBr in ozonated waters.\(^{(6)}\) The method used methyl tert-butyl ether (MTBE) (CAS 1634-04-4) as the extraction solvent, sodium sulfate as the supplemental salt to increase the extraction efficiency, and GC/ECD for separation and detection. This method was further developed and expanded for analysis of both CNCl and CNBr in chloraminated waters.\(^{(7)}\) A similar method was also developed for CNCl analysis,\(^{(23)}\) where cyclohexane was used as the extraction solvent.

4.3.2 Sample Preparation and Analysis

Prior to sample extraction, bring the samples to room temperature. Use 40-mL glass vials with PTFE-faced septa and screw caps for the sample extraction. To a vial containing a 30-mL aliquot of sample, add 10 g of Na\(_2\)SO\(_4\) and 4 mL of MTBE spiked with 100 µg L\(^{-1}\) internal standard, 1,2-dibromopropane. Shake once or twice to disperse the salt and then proceed to the next
4.3.3 Discussion

A typical gas chromatogram of 10 µg L⁻¹ of extracted CNCl, CNBr, and calibration standard (1,2-dibromo-propane) is shown in Figure 8.(7) All three components are well separated. The GC run time was less than 14 min. A linear calibration curve ranging from 0.5 to 24 µg L⁻¹ was obtained for CNCl with an R² value of 0.9993, and second-order polynomial calibration curves ranged from 0.5 to 24 µg L⁻¹ for CNBr with an R² value of 0.9993. The method detection limits for CNCl and CNBr were 0.13 and 0.26 µg L⁻¹. By analyzing 10 treated surface water samples spiked with 5–7 µg L⁻¹ of CNCl or CNBr the mean recovery for CNCl was 98 ± 6.3%, whereas the mean recovery for CNBr was 100 ± 10%. In another study, the quantitation limit for CNCl was estimated at 0.5 µg L⁻¹.(18)

Four organic solvents were studied by Sclimenti et al.(7) Both hexane and isooctane co-eluted with CNCl and could not be used as the extraction solvents. Pentane extracted both CNCl and CNBr well. In comparison with pentane, however, MTBE gave a better extraction for CNBr, giving a similar extraction efficiency for CNCl. Therefore, the micro LLE GC/ECD method uses MTBE as the extraction solvent.

The effects of a salt, sodium sulfate, and shaking time on the extraction efficiency were also studied.(7) Addition of Na₂SO₄ at a concentration range from 5 g to 12 g per 30-mL aliquot increased the extraction efficiency of CNCl. However, CNBr recoveries began to diminish at the same salt concentration range. This may be due to trace levels of nucleophiles which adversely affect the stability of CNBr.(18) For the LLE GC/ECD method, a salt concentration of 10 g of Na₂SO₄ per 30-mL of aliquot and a shaking time of 10 min were chosen. These parameters represent a compromise among the conditions that were most suitable for each analyte separately.

The micro LLE GC/ECD method is efficient for simultaneously determining both CNCl and CNBr in chloraminated waters. The method performance study showed a high degree of precision and accuracy. Compared to the

PT GC/MS system, the GC/ECD is a much more common system in most water-testing laboratories. The downtime for GC/ECD is significantly less than for GC/MS. Compared to the headspace GC/ECD method, the LLE sample injection could be easily automated with a liquid autosampler.

5 SUMMARY

Both LLE GC/ECD and headspace GC/ECD are viable methods for determining CNCl and CNBr in drinking water. Selection may depend upon the resources of the particular laboratory. The PT GC/MS method (modified USEPA 524.2) can be efficiently used to analyze for CNCl, especially when other volatile solvents are also being determined and when mass spectral identification is desired.

With increasing concern over chemicals that are potential health hazards at low levels, determination of limits of detection and quantification have undergone considerable scrutiny. Most traditional detection limit (DL) estimators suffer from extensive statistical and/or conceptual limitations. In this article, traditional detection and quantification limit estimators are described and critically evaluated. Methods are categorized into decision limits, DLs and quantification limits. The methods are further categorized into single concentration design versus calibration design methodologies. While the single concentration design methods are useful for fixing ideas and clarifying definitions they are shown to be extremely limited in practice since dependence of variability on concentration can be neither estimated nor incorporated. Calibration-based detection and quantification limit estimators are described, compared and contrasted. Discussion of nonconstant variance, multiple future detection decisions and simultaneous control of Type I and II errors is provided. The various methods are illustrated using real data and experimental design issues for DL studies discussed.

1 INTRODUCTION

Of critical concern in protection of human health and the environment is the earliest possible detection of hazardous environmental constituents (i.e. air, surface water, groundwater, drinking water). The very presence of anthropogenic compounds in environmental media may lead to assessment and potential remediation of industrial activity. As an example, the presence of vinyl chloride, a known carcinogenic initiator, in a groundwater sample obtained from a monitoring well located downgradient of a hazardous or municipal waste-disposal facility may result in an expensive site assessment, possible corrective action or closure of the facility. In some cases, these consequences may be the result of a single detection decision in a single environmental sample. In other cases, the measured concentration of a constituent is compared with a concentration limit, possibly health-based, and if the measured concentration exceeds the limit, remedial action is taken. Unfortunately, in many cases the limit of detection for the constituent in a particular medium (e.g. surface water) is reported to be considerably larger than the health-based concentration limit. There is public concern regarding protection of human health and the environment in that potentially harmful levels of a chemical may exist in the environment but since they are undetectable no regulatory impact decision can be made.

In response to these concerns there has been tremendous motivation to develop new analytical methods capable of detecting these compounds at lower levels. Furthermore, these concerns have led to a proliferation of new definitions and statistical approaches to estimating limits of detection. These new definitions and statistical estimators often lead to further confusion and suffer from statistical and conceptual errors. New methods proposed for setting limits on detection may result in lower limits regardless of the actual analytical capabilities of the method.

Unfortunately, virtually all practical applications of environmental detection decisions in the United States are based on the most severely limited of the definitions.\cite{4,5} They are carried out by the United States Environmental Protection Agency (USEPA). Not only are the statistical problems with USEPA’s estimator, termed the method detection limit (MDL), insurmountable but the use of this estimator has led to the routine practice of setting DL at lower and lower levels regardless of the true analytical capabilities of the method and/or laboratory. The purpose of this article is to illustrate these statistical limitations and to provide a review of less problem-prone alternative estimators. To do so, this article reviews a variety of methods from both statistical and conceptual frameworks. The intended audience is both the statistician interested in environmental applications and the environmental scientist interested in the conceptual and statistical foundations of limits of detection. Public policy in these areas has not been adequately examined in either the statistical or chemometric literatures.

There are a myriad of terms for limits of detection: MDL, DL, instrument detection limit (IDL), practical method detection limit (PMDL) etc. However, their conceptual foundations as well as implementation algorithms are often quite diverse, leading to tremendous inconsistency in practice. To provide a framework to compare and contrast these various methodologies the pioneering definitions of Currie\cite{6} are used, since they form the basis of most approaches. Currie defined two levels; the “decision limit” and the “DL.” The decision limit is the measured concentration “at which one may decide whether or not the result of an analysis indicates detection”.\cite{6} The DL is the true concentration “at which a given analytical procedure may be relied upon to lead to a detection”.\cite{6} From a statistical perspective, the decision limit is the critical value for a test of the null hypothesis “analyte absent” versus the alternative hypothesis “analyte present”. Note that the DL is a direct function of the selection of the critical value.

Operationally, the decision limit or critical level \(L_D\), is the measurement above which the response signal significantly differs from zero. When a measurement exceeds \(L_D\) we can make the binary decision, “detected”. Note that when the true concentration is zero, the probability of the correct decision, “not detected” is \(1 - \alpha\) where \(\alpha\) is the Type I error rate or false positive rate of the statistical test (e.g. \(\alpha = 0.01\)). Assuming a symmetric distribution of measurement errors, when the true concentration is equal to \(L_C\) the probability of reporting it below \(L_C\) is 50%. This is termed the Type II error rate or false negative rate (\(\beta\)). To control both Type I and II errors Currie then developed the DL \(L_D\). When the true concentration is \(L_D\), then the Type II error rate (\(\beta\)) using \(L_C\) as the decision limit is small. For example, if we assume that \(\alpha = \beta = 0.01\), then another way of stating this is that 99% of the measurements for samples not containing the analyte will be less than the decision limit \(L_C\) and 99% of the measurements with true concentration at the DL \(L_D\) will exceed the decision limit \(L_C\).\cite{7}

Investigators have defined the limit of detection to include control of both false positive and false negative rates, varying levels of confidence, uncertainty in the concentration mean and variance and in the calibration function that relates instrument response to concentration, variance components related to multiple instruments and analysts, application to multiple future detection decisions, and nonconstant variance and baseline instrument response.\cite{1,6,8-12} However, these operational definitions may cloud the distinction between decision limits and DLs (as an example see Glaser et al.\cite{5})

An alternative approach and review of many of these issues can be found in Lambert et al.\cite{7} and Hastie and Tibshirani.\cite{13} The method introduced by Lambert et al. provides much information regarding the statistical properties of low-level analytical measurements conditional on a fixed and pre-existing method of making binary detection decisions, but does not provide an independent estimate of the limit of detection. In a sense, Lambert’s method models the detection criterion of the analyst but not the actual capabilities of the analytical method itself.

In the following sections we examine the strengths and weaknesses of a variety of approaches to the problem of estimating limits of detection in use or proposed for widespread application. These approaches fall into two general categories; single concentration-based methods and calibration-based methods. Methods based on single concentration designs are useful for fixing ideas and definitions, particularly the critical distinction between decision limits and DLs. In general single point designs lead to problems which severely limit their use in practice which can be eliminated through use of calibration-based methods. These methods are fully described and classified as decision limits or DLs. Generalization of calibration-based methods to problems of nonconstant variance, multiple future detection decisions and alternative approaches to controlling Type I and II error rates are presented. Application of the various methodologies are illustrated using real data and experimental design considerations are discussed. Following discussion of DLs, various estimators of the quantification limit are described and illustrated.

### 2 DETECTION LIMITS FOR SINGLE CONCENTRATION DESIGNS

Single concentration designs involve spiking a series of \(n\) samples with a fixed concentration of a compound...
and using variability in instrument response at that concentration to derive a decision limit, DL or both. In the following, the major strategies for estimating decision limits and DLs from single concentration designs are described.

### 2.1 Kaiser–Currie Method

Based on developments due to Kaiser\(^{14–16}\), Currie\(^6\) described a two-stage procedure for calculating the DL \(L_D\). At the first level of analysis, Currie computes the decision limit \(L_C\) (Equation 1) as:

\[
L_C = z_{1-\alpha} \sigma_0
\]

(1)

where \(\sigma_0\) is the population standard deviation of the response signal when the true concentration \(x\) is zero (i.e. the standard deviation of the net signal found in the population of blank samples), and \(z_{1-\alpha}\) is a multiplication factor based on the \((1-\alpha)100\) percentage point of the standardized normal distribution.

For example, the one-sided 99% point of the normal distribution is 2.33; therefore, the decision limit (Equation 2) for a 1% false positive rate is defined as:

\[
L_C = z_{1-\alpha} \sigma_0 = 2.33 \sigma_0
\]

(2)

As discussed, when the true concentration is equal to \(L_C\) and the measurement error distribution is symmetric, the Type II error rate at the decision limit is 50%. That is, we have a 50% chance of declaring that the analyte is not present when the analyte in fact is present at the decision limit. To provide an acceptable Type II error rate, Currie defined the DL \((L_D)\) (Equation 3) as

\[
L_D = L_C + z_{1-\beta} \sigma_D
\]

(3)

where \(\sigma_D\) is the population standard deviation of the response signal at \(L_D\) (or net response signal after subtracting the background signal), and \(\beta\) is the acceptable Type II error rate (i.e. false negative rate).

Currie points out that if we make the simplifying assumption that \(\sigma_0 = \sigma_D\) (i.e. the variability of the signal is constant in the range of \(L_C\) to \(L_D\)) and that the risk of false positive and false negative rates is equivalent (i.e. \(z_{1-\alpha} = z_{1-\beta} = z\)) then the DL is simply (Equation 4):

\[
L_D = L_C + z_\beta \sigma_D = z(\sigma_0 + \sigma_D) = 2L_C
\]

(4)

or twice the decision limit. For \(\alpha = \beta = 0.01\), the DL is therefore 4.66\(\sigma_0\). If the true concentration is \(L_D\) then the probability of a measured valued below \(L_C\) is 1%.

In reviewing Currie’s method it is critically important to note that the only case considered is the one in which the population values \(\sigma_0\) and \(\sigma_D\) are known. In practice, however population values are never known and the methods described in following sections are required to incorporate uncertainty in sample-based estimates of these statistics in decision-limit and DL estimates.

### 2.2 United States Environmental Protection Agency 40CFR 136

Glaser et al\(^5\) defined the MDL as “the minimum concentration of a substance that can be identified, measured and reported with 99% confidence that the analyte concentration is greater than zero”, and that “on average, 99% of the trials measuring the analyte concentration of the MDL must be significantly different from zero”. The first definition is in terms of true concentration and could therefore be interpreted as \(L_D\). Similarly, if one interprets “significantly different from zero” as greater than \(L_C\), which is reasonable, then the MDL as conceptually defined is also consistent with \(L_D\). Unfortunately, their derivation converges asymptotically to an estimate of the 99th percentile of the distribution of measurements at concentration \(x = 0\), which is, of course, \(L_C\). These definitions have been adopted by USEPA\(^4\) and the MDL is used in establishing all published DLs under USEPA regulations for environmental monitoring of drinking water, groundwater and surface water. In addition, all laboratories performing analyses under these regulations must be certified on the basis of meeting published MDLs using this method.

In constructing a model for the MDL, Glaser et al\(^5\) initially assume that variability is a linear function of concentration, (Equation 5) such that:

\[
s_x = b_0 + b_1 x
\]

(5)

where \(s_x\) is the standard deviation of \(n\) replicate analyses at concentration \(x\) and \(b_0\) and \(b_1\) are the intercept and the slope of the linear regression of standard deviation on concentration. They define the MDL (Equation 6) to be that concentration \(x\) for which:

\[
t_x = \frac{x}{s_x/\sqrt{n}}
\]

(6)

holds when \(t\) is set equal to the 99th percentile of Student’s \(t\)-distribution with \(n-1\) degrees of freedom. At this point Glaser et al. make two simplifying assumptions. First, they set \(b_1\) to zero, therefore (Equation 7):

\[
\text{MDL} = \frac{t_{0.01,n-1} b_0}{\sqrt{n}}
\]

(7)
Second, they assume that \( s_x = b_0 / \sqrt{n} \), therefore (Equation 8):

\[
\text{MDL} = t_{[0.01, n-1]} s_x
\]

where \( s_x \) is defined as the standard deviation of \( n \) analytical replicates spiked at a single concentration \( x \).

There are numerous problems with this model. First, having started with a conceptual definition that sounds promisingly like \( L_D \) they derive a mathematical definition that corresponds to \( L_C \). This highlights the major distinction between the MDL and the other methods reviewed here. Second, having started with the useful generalization, variance allowed to be a function of concentration, they remove it by assuming \( b_1 = 0 \) and using a single concentration to estimate \( s_x \). To estimate \( b_0 \) and \( b_1 \) would require multiple samples at each of several concentrations (i.e. a calibration design). Third, there are inexplicable inconsistencies about whether \( s_x = b_0 \) (per Equation 6 after you set \( b_1 = 0 \)) or \( b_0 / \sqrt{n} \) as asserted in the sidebar in Glaser et al.\(^{5}\) Of course, \( b_0 / \sqrt{n} \) is the standard error of measurement at \( x = 0 \), not the standard deviation at concentration \( x \).

It seems odd that the initial assumption of this model is that variability is dependent on concentration, yet in practice the observed standard deviation for seven replicates is used regardless of the concentration at which the sample is spiked. In practice, laboratories demonstrate they can achieve low state and federally mandated MDLs (used as decision limits, not DLs) by spiking at progressively lower concentrations. Glaser et al. suggest that the spiking concentration should be close to the “true MDL”; however, since the true MDL is unknown, the spiking concentration is often set at risk-based standards (e.g. a maximum contaminant level – MCL) and can be well below the true MDL. Since Glaser et al. assume that the \( s_x \) is a linear function of concentration, this practice can lead to a gross underestimate of the true MDL.

It should be noted that despite the obvious limitations of the statistical derivation of the MDL, the underlying conceptual framework foreshadows some of the ideas of calibration designs. Conceptually, the underlying model assumes that the measured value is normally distributed with mean equal to the true concentration \( x \) and standard deviation \( b_0 + b_1 x \). This conceptual model leads directly to many of the statistical results for calibration designs but is intractable for single concentration designs since \( b_0 \) and \( b_1 \) are unknown and cannot be estimated from a single concentration. Unfortunately, USEPA continues to use the MDL as the basis for regulatory detection decisions. The MDL also forms the basis for the new approach USEPA has taken to quantification, the minimum level (ML) which is computed as 3.18 MDL.\(^{17}\)

### 2.3 Prediction Limits

Prediction limits were apparently not considered in the context of single concentration designs. Nonetheless they are more relevant to making detection decisions than either the MDL or the Kaiser–Currie method. A prediction limit provides a certain level of confidence (e.g. 99%) of including the next single measurement based on a previous sample of \( n \) measurements. If we consider a single future detection decision, then the decision limit (Equation 9) based on a prediction limit\(^{18}\) for a normally distributed instrument response is

\[
L_C = t_{(n-1, \alpha)} s_D \sqrt{1 + \frac{1}{n}}\]

where \( s_0 \) is an estimate of \( s_0 \) (i.e. the standard deviation in blank samples). For the seven replicate samples required by USEPA, the decision limit (Equation 10) becomes

\[
L_C = 3.14 s_0 \sqrt{1 + \frac{1}{7}} = 3.36 s_0
\]

where \( \alpha = 0.01 \). Assuming \( s_0 = s_D = s \) and \( \alpha = \beta \) the DL (Equation 11) can be approximated by

\[
L_D = 2 t_{(n-1, \alpha)} s \sqrt{1 + \frac{1}{n}} = 2L_C
\]

however, this is an invalid use of the central \( t \) distribution since the statistic \( \sqrt{n} x / s \) has a noncentral \( t \) distribution when \( x > 0 \) (i.e. in computing \( L_D, x = L_C \)).

### 2.4 Tolerance Limits

In practice, a limit of detection is computed and applied to a large and potentially unknown number of future detection determinations. As such, the prediction limit described in the previous section may not be relevant to many situations because the error rate pertains to a single future detection decision. An alternative is to use the decision limit on a statistical tolerance limit that will contain a proportion of all future measurements (e.g. 99%) with a specified level of confidence (e.g. 99%). Tolerance limits are well known in the statistical literature and have been described in detail by Guttmann\(^{19}\) with corresponding tables relevant to this application. In this context (Equation 12), the decision limit becomes

\[
L_C = K_{(p, \alpha)} s_0
\]

where values of \( K \) for varying coverage proportions (P) and confidence levels \( 1 - \alpha \) are available in tabular form.\(^{11,18,19}\)

Following USEPA guidance using seven replicate samples, the decision limit would be 6.41s_0, and would provide 99% confidence of including 99% of all future
measurements when the true concentration is zero. Of course, as the number of background samples increases, the size of the multiplier decreases. Use of tolerance limits to compute the DL is not straightforward; however, an approximate method has been developed.\(^{(10)}\)

### 2.5 Simultaneous Control of False Positive and False Negative Rates

The distinction between decision limits and DLs is based on simultaneous control of both false positive and false negative rates. When the population parameters \(\sigma_0\) and \(\sigma_D\) are known, as was assumed by Currie, repeated application of the normal multiplier \(z_{1-\alpha}\) followed by \(z_{1-\beta}\) is appropriate. In practice however, \(\sigma_0\) and \(\sigma_D\) are unknown and are replaced by their sample-based estimates \(s_0\) and \(s_D\) provided by a sample of \(n\) spiked measurements. In this case repeated application of Student’s \(t\) distribution (i.e. \(t_{1-\alpha}\) and \(t_{1-\beta}\)) is incorrect.

In computing \(L_C\), the true concentration \(x = 0\) and the false positive rate of the decision limit is based on Student’s \(t\) distribution. In computing \(L_D\) the true concentration \(x = L_C\) and the statistic \(\sqrt{n}/s_0\) has a noncentral \(t\) distribution on \(n - 1\) degrees of freedom.\(^{(1,10)}\) Relevant tabled values of the noncentrality parameters \(\phi(n - 1, \alpha, \beta)\) are also available.\(^{(1,10)}\) For the case of \(n = 7\) measurements and false positive and false negative rates of 1%, the limit of detection is \(\phi(6, 0.01, 0.01)s_0 = 6.64s_0\). Although this limit of detection considers both false positive and false negative rates it pertains only to a single future detection decision. Gibbons et al.\(^{(10)}\) have further generalized the result to include coverage of a specified proportion of all future values and have provided a corresponding table of multipliers (also see Gibbons\(^{(11)}\)).

### 2.6 Limitations

The critical assumption underlying single concentration designs is that variability is homogeneous in the range of possible spiking concentrations and the true limit of detection. This assumption is implicit in the use of observed spiking concentration variance as an estimator of the true variance at the limit of detection. This assumption is rarely realized in practice. As a typical example, consider the calibration function presented in Figure 1.

For the purpose of illustration, actual concentrations are presented on the \(x\)-axis and measured concentrations are presented on the \(y\)-axis. In practice, the \(y\)-axis should represent actual peak area ion counts prior to calibration. Ignoring this step will lead to ignoring uncertainty in the calibration function, never known with certainty.

Figure 1 displays calibration data for silver using USEPA Method 1638\(^{(20)}\) in distilled water. These data were obtained under controlled nonblind conditions that are not representative of routine practice. Spiking concentrations were 0, 10, 20, 50, 100, 200, 500, 1000 ppt. The center line that passes through these data represents the weighted least squares (WLS) estimate of the linear calibration regression line. The curvilinear functions that provide an interval surrounding the data are WLS prediction bands and provide 99% confidence of including the next single measurement at a given concentration.

![Figure 1](image-url)  
*Figure 1 Linear calibration assuming increasing variance based on Rocke and Lorenzato Model: Method 1638 Silver (ppt) – prediction interval.*
was observed for each of 8 other compounds. The prediction bands, which are based on the assumption that variability increases with concentration, fit the observed measurements extremely well. Of the 56 measurements (i.e., 7 replicates of each of the 8 spiking concentrations) one measurement is beyond the prediction bands, and therefore consistent with the 99% confidence level. The implication of this finding is that the driving force behind limits of detection from single concentration designs is the concentration at which the samples are spiked. To illustrate this point, Table 1 displays the USEPA/Glaser et al. MDL estimator applied to the data in Figure 1 at various concentrations.

Table 1 reveals that USEPA’s MDL estimator will yield values ranging from 67.29 ppt to 1.47 ppt from exactly the same data. If a new analytical method with lower limits of detection were developed, presumably it would be tested by spiking at a correspondingly lower concentration. Thus, regardless of the true analytical properties of the method a lower MDL will be found.

Anticipating this problem to some extent, Glaser et al. suggest both a single-step and an iterative approach to computing the MDL (also described in USEPA’s adoption of the procedure). For the single-step approach they recommend spiking samples at a concentration between one and five times the best estimate of the true MDL. They note that it is possible that an incorrect MDL could be obtained even if the spiking concentration were less than five times the computed MDL, illustrated in the higher values in Table 1. This logic requires that we know the actual MDL, which never happens in practice. In this case they recommend an iterative approach in which successively lower concentrations are computed until the pooled variance stabilizes. They note that convergence of the iterative procedure depends on the closeness of the estimated MDL to the calculated MDL. They also note that if the calculated MDL is lower than the background level of the analyte, the iterative procedure cannot be used.

Inspection of Table 1 reveals that spiking concentrations of 200 ppt and 10 ppt both meet USEPA’s criterion of a spike to MDL ratio of 5:1 or less. Presumably, if we had started at higher concentrations and iteratively decreased the spiking concentration we would obtain an MDL of 48 ppt. Alternatively if we started at zero and worked up, we would have obtained an MDL of 2 ppt. This level of arbitrariness is unacceptable in a DL estimator and can lead to both false positive and false negative regulatory impact decisions based on samples spiked at higher or lower concentrations. For this reason, single concentration decision limits and DLs are of little practical value despite their widespread use.

3 DETECTION LIMITS FOR CALIBRATION DESIGNS

An alternative method for estimating DLs is a calibration design. In this case, a series of samples are spiked at known concentrations in the range of the hypothesized DL, and variability is determined by examining the deviations of the actual response signals from the fitted regression line of response signal on known concentration. In these designs, it is generally assumed that the deviations from the fitted regression line are normally distributed.

There are two major advantages of calibration designs over single concentration designs. First, single concentration designs ignore uncertainty in the calibration function that relates measured to true concentration. Second, when variability in measured concentration is a function of true concentration, the estimated DL, based on a single concentration design, will depend in large part on the spiking concentration selected by the analyst. If different laboratories select different spiking concentrations, it will appear that they have different analytical capabilities when they may, in fact, be identical. This is not a problem for calibration-based DLs since the relationship between variability and concentration can be explicitly modeled and incorporated into the DL estimator.

Proponents of single concentration designs suggest that nonconstant variance can only lead to overestimates of the true DL since variability at a concentration greater than zero will be larger than the variability when the analyte is absent. In many cases this is true, and artificially high DLs can result. However, if a very low spiking concentration is selected, gross underestimation of the DL is also possible. Modern analytical instruments are often designed to censor measured concentrations less than zero. If the spiking concentration is close to zero, then we would expect up to 50% of the measured concentrations to be negative. However, if the instrument assigns a concentration of zero to these samples, the estimated
standard deviation will be a gross underestimate of the true population standard deviation. To make matters worse, many instruments use peak area rejection criteria so that even positive concentrations of low magnitude will also be assigned a measured concentration of zero. Again, this practice will lead to even further underestimates of variability and corresponding DLs. Calibration designs are immune to such problems since concentrations both above and below the true DL are included and nonconstant variance accommodated. The primary disadvantage of calibration based DL estimators is that they are more complicated to compute and typically will require a computer program capable of unweighted least squares (ULS) regression and/or WLS regression. Fortunately computer programs for these computations are now becoming readily available.(21,22)

Hubaux and Vos(8) were the first to describe a procedure for calibration based DL estimation. Beginning from a calibration design in which response signals are determined for analyte-containing samples with concentrations throughout the range of \( L_C \) to \( L_D \), they constructed a 99% prediction interval for the calibration regression line (see Figure 2). The prediction interval is given by Equation (13):

\[
\hat{y}_x \pm t_{(1-\alpha/2, n-2)} s(\hat{y}_x)
\]

where \( s(\hat{y}_x) \) is the estimated uncertainty of a predicted instrument response (or measured concentration) \( \hat{y} = b_0 + b_1 x \) at true concentration \( x \) (see Appendix). The DL is defined as the point at which we can have 99% confidence that the response signal is greater than \( L_C \); therefore, Hubaux and Vos suggest that the response signal be obtained graphically by locating the abscissa corresponding to \( L_C \) on the lower prediction limit (see Figure 2). A more direct solution for \( L_D \) is provided in the technical Appendix.

The method of Hubaux and Vos assumes that variability is constant throughout the range of concentrations used in the calibration design. If this assumption is violated, then the DL will be overestimated because variability at high concentrations are given equal weight as those at lower concentrations. Clayton(1) suggested a variance-stabilizing square-root transformation which helps to some extent but does not eliminate the problem. Oppenheimer(23) proposed an estimator of \( L_D \) based on WLS regression which provides a general solution to this problem but requires an iterative solution (see Appendix 1). Gibbons et al.(10) provide a noniterative computing approximate and further generalize this result to the case of multiple future detection decisions by substituting tolerance limits for prediction limits. See Gibbons(3,11) for a review of this literature.

3.1 Illustration

Figures 1–5 display actual and measured concentrations of silver in seven eight-point concentration calibrations. Figure 2 represents the same data as in Figure 1, but assumes constant variance and provides corresponding Hubaux–Vos estimates of \( L_C \) and \( L_D \). Figure 2 reveals that if we assume constant variance, in order to incorporate larger variability at higher concentrations, variability is overestimated at the lower concentrations. In contrast, the WLS approach described in Figure 1 provides excellent fit to the observed data for both high and low true concentrations. Figure 3 represents the same data as Figure 1 but shows error bands based on a statistical tolerance interval with 95% confidence and 99% coverage. Figure 3 reveals that substitution of tolerance
Table 2 presents estimated DLs for several of the previously described approaches.

Inspection of Table 2 reveals that, as expected, the Hubaux–Vos ULS approach assuming constant variance yields a much higher DL than the WLS approaches which assume that variability is an increasing function of true concentration. Once nonconstant variability is accounted for, we pay a very modest price for generalizing the limits to apply to 99% of all future detection decisions as opposed to the next single detection decision (e.g. 5.6 ppt versus 3.6 ppt). The approximate noniterative solution suggested by Gibbons et al. works well in this example. Note that the calibration-based estimates of $L_C$ and $L_D$

appear to be quite reasonable given the data displayed in Table 1. Note that these data were obtained under highly controlled "clean lab" research conditions in distilled water and the DLs obtained here may be considerably higher in routine practice. Nevertheless, these results clearly reveal that calibration-based methods do not necessarily lead to higher DL estimates than their single concentration counterparts (e.g. the MDL).

4 EXPERIMENTAL DESIGN OF DETECTION LIMIT STUDIES

A detailed review of the principles of experimental design of DL studies would easily require a chapter to itself and has been reviewed in some detail by others.<sup>12,24</sup> There are several guiding concepts critical for producing unbiased DL estimates of practical relevance.

First, in analyte present studies, the analysts must be blind to both the number of compounds in the sample and to their spiking concentrations. To achieve this goal, the number of compounds must vary (perhaps randomly) from sample to sample. Furthermore, the concentration of each constituent should vary both within and across samples. Without ensuring that the analyst is blind to both presence and concentration of the analyte under study, the resulting DL simply cannot be applied to routine practice in which such uncertainty must always exist. In practice, it is often impossible to execute such studies since numerous samples would have to be prepared at widely varying concentrations. In the absence of this level of experimental control, standard calibration data in which the analysts are unaware that they are being tested may have to suffice. The critical issue is that the analysts must not go back and retest samples that appear to be anomalous relative to the known spiking concentration.

Second, two or more instruments and analysts must be used and the assignment of samples to analysts and instruments must also be random. Since in large production laboratories, any one of a number of analysts and/or instruments may be called upon to analyze a test sample, this same component of variability must be included in determining the DL.

Third, if multiple laboratories are used or a regulatory agency analyzes split-samples or additional samples from the facility, then the entire DL study must be replicated in multiple laboratories. Data from a single laboratory should only be used when it is technically unfeasible to provide common calibration standards, or to split common standard samples, or a dedicated laboratory is used for all relevant analyses.

Fourth, the number of samples selected should be based on statistical power criteria, such that a reasonable
balance of false positive and false negative rates is achieved. For example, if we estimate $\sigma$ by computing $s$ on seven samples, our uncertainty in $\sigma$ will be extremely large and our resulting DL estimate $L_D$ will also be quite large. By increasing the number of samples to say, 25, we achieve a much more reasonable estimate of $\sigma$, and resulting $L_D$ are greatly reduced. The cost of running a few additional samples is far cheaper than dealing with the drawbacks of using DLs incapable of detecting anything but the largest signals.

An additional note regarding analyte-absent experiments (i.e. blank samples): rather than running a series of blank samples at once, they should be randomly entered into the analysts’ work load throughout the course of the day. The purpose of this approach is to ensure that the analysts are blind to sample composition. The broader question is whether analyte-absent experiments are relevant to establishing DLs. It can be argued that the properties of the method can only be evaluated when the analyte is present, at least in some of the samples. The general recommendation of calibration designs over fixed-concentration designs allows for a mixture of samples in which the analyte is present and absent.

There are several experimental designs that can fulfill the preceding requirements. When the number of samples is large, say $n = 30$, one possibility is to give each compound in the study a 0.5 probability of being in any given sample, and once selected, its concentration could also be randomly selected from a uniform distribution covering the range of 0 to $2L_D$, where $L_D$ is the presumed DL. This design may be optimal to ensure blindness, but it may not be necessary to maximize the signal-to-noise ratio which increases the amount of information gained in such a study. For example, Hubaux and Vos(8) suggest a three values repartition, in which $n_1$ replicate samples at the lowest permissible content ($x_1$), $n_2 = n - n_1 - 1$ samples at the highest “permissible content” ($x_2$) and a single sample at $(x_1 + x_2)/2$ are selected. They find that this design minimizes the number of required standards for a fixed level of sensitivity.

Liteanu and Rica,(24) review a wide variety of sampling designs for DL studies, including response surface designs, fractional factorial designs and rotatable designs. Youden pair-type designs are excellent candidates for maintaining blind and unbiased DL studies.

Finally, in any design in which there are multiple components of variability (e.g. analyst, instrument, laboratory), appropriate steps must be taken to obtain unbiased estimates of variability. The naive estimator of $\sigma$ which is obtained by computing $s$ in the usual way with all measurements should be replaced by the unbiased variance estimate based on the appropriate variance components model for the problem at hand.(25,26)

5 Quantification Limits

Quantitative determination in analytical chemistry is a two-stage process. First, we must make the binary decision of whether or not the compound is present in the sample. Second, in the event the compound is present, we must determine if the estimated concentration supports quantitative determination. The first determination is governed by the DL as discussed in the previous sections. In contrast, very little literature exists on the second stage of the decision process, i.e. quantification. Currie(6) originally described the “determination limit” ($L_Q$) as the concentration at which the relative standard deviation (RSD) is 10% (i.e. a signal-to-noise ratio of 10 to 1). Gibbons et al.(27) have provided a more statistically rigorous estimator of $L_Q$ that accommodates effects of nonconstant variance, uncertainty in the parameters of the recovery curve and uncertainty in the sample-based estimator of the true population variance. More recently, USEPA(17) has defined the ML as the method DL (defined in 40CFR Part 136 App. B(4)) multiplied by a factor of 3.18. USEPA is using the ML as a quantification limit above which measured concentrations can be directly compared to regulatory standards and compliance decisions can be made. In an attempt to provide an estimator that is conceptually similar to the ML, but with fewer statistical limitations, Gibbons et al.(28) have developed an “Alternative Minimum Level” (AML). In the following, strengths and weaknesses of these various alternatives are explored.

5.1 The United States Environmental Protection Agency Minimum Level

USEPA(17) has defined the ML (Equation 14) as:

$$ML = 3.18 \cdot (3.18) = 10s_x$$

where $s_x$ is the standard deviation of 7 replicate measurements spiked at true concentration $x$. All limitations previously described for the USEPA MDL apply equally to the ML since it forms the basis for this estimator, i.e. the MDL and hence the ML is a direct function of the choice of spiking concentration $x$. In addition, it is of critical importance to understand that the ML is not based on the permittee’s MDL, but rather on a single MDL developed by a single USEPA laboratory under ideal conditions. This further reduces generalizability of the ML to application under routine conditions in which analysts are blind to the true concentration and any one sample can be analyzed by different analysts, instruments and even laboratories.
5.2 Alternative Minimum Level

The fundamental problem with the ML is not its definition (i.e. 10%) but the fact that the sample standard deviation $s_x$ is a moving target and depends completely on the choice of spiking concentration $x$. As previously noted, the ML suffers from numerous other problems in that it completely ignores interinstrument, interanalyst and interlaboratory components of variation, but this has more to do with the way in which USEPA has applied the method and not the statistical derivation itself. It is the statistical derivation that we focus on in developing the AML.

As a conceptual foundation, Currie defined the determination limit $L_Q$ (Equation 15) as

$$L_Q = 10\sigma_Q$$

where $\sigma_Q$ represents the true population standard deviation at the determination limit $L_Q$. The $L_Q$ is based on the idea that quantitative determinations can be confidently made when the signal-to-noise ratio is ten to one (i.e. a RSD of 10%). Unfortunately, in the real world, we never know the population standard deviation (i.e. it must be estimated from a sample of $n$ measurements) and in many cases, the proportionality constant between the standard deviation and concentration is larger than 10% in the practical calibration range and therefore a 10% RSD may not be achievable or only achievable at unacceptably high levels.

A reasonable alternative to both approaches is to compute the standard deviation at the lowest concentration that is differentiable from zero and use that standard deviation in computing the ML. In this way, the spiking concentration is no longer arbitrary and the effect of nonconstant variance is incorporated up to the lowest nonzero concentration. Of course, this alternative ML (AML) will not guarantee a 10%RSD at the AML; however, we can compute the actual %RSD at the ML by modeling the association between $s$ and $x$. The algorithm is as follows:

1. Using calibration data, model the relationship between $s$ and $x$, for example an exponential function (Equation 16)

$$s_x = a_0 e^{a_1(x)}$$

The exponential model $s_x = a_0 e^{a_1x}$ generally provides excellent fit to the observed data and it will be used in the following discussion. However, the model suggested by Rocke and Lorenzato (Equation 19) is also an excellent choice. The Rocke and Lorenzato model was used in generating the prediction intervals in Figure 1. The exponential model can be fitted using nonlinear least squares (e.g. Gauss–Newton) or by ULS regression of natural log transformed measured concentration on actual concentration (Snedecor and Cochran, p. 397(30)).

2. Compute the WLS regression of measured concentration or instrument response ($y$) on true concentration ($x$) for the linear model (Equation 17)

$$\hat{y} = b_{0w} + b_{1w} x_i$$

as described in Appendix 1.

3. Iteratively compute the $L_C$ using the method originally proposed by Scott et al.(12) which is the upper 95% confidence 99% coverage tolerance limit for measured concentrations when the true concentration is zero, (Equation 18):

$$y_C = K_{0.95,0.99} b_{0w} + b_{1w}$$

where $K_{0.95,0.99}$ is the 95% confidence 99% coverage one-sided normal tolerance limit factor for $n$ observations, where, in this case, $n$ is the total number of measurements (see Table 4.2 in Gibbons(11)). $L_C$ is the corresponding true concentration (Equation 19):

$$L_C = \frac{y_C - b_{0w}}{b_{1w}}$$

Note that although it is not required for computing the AML, a Currie-type estimate of the DL ($L_D$) can also be obtained by iteratively computing Equation (20):

$$y_D = y_C + K_{0.95,0.99} b_{1w}$$

and $L_D$ is the corresponding true concentration (Equation 21):

$$L_D = \frac{y_D - b_{0w}}{b_{1w}}$$

4. Compute the standard deviation at the $L_C$ from Step 1 (i.e. $s_{L_C}$), for example (Equation 22):

$$s_{L_C} = a_0 e^{a_1(L_C)}$$

5. Compute the measured concentration at ten times the standard deviation at the $L_C$ (Equation 23):

$$y_Q = 10s_{L_C} + b_{0w}$$

6. The AML is then computed as Equation (24):

$$x_Q = \left( \frac{t}{b_{1w}} \right) \sqrt{V(y_Q)}$$
where \( x_Q = (y_Q - b_{0w})/b_{1w} \). The value \( t \) is the upper 99th percentile of Student’s \( t \) distribution on \( n - 2 - p \) degrees of freedom, where \( p \) is the number of unknown parameters in the standard deviation model. Alternatively when \( n \) is large (e.g. \( n > 25 \)) the AML can be approximated by Equation (25):

\[
AML \sim \left( \frac{x_Q + tsx_Q}{b_{1w}} \right)
\]

(25)

### 5.3 Illustration

To illustrate the computation of the AML, return to the data in Figure 1. Inspection of Figure 6 reveals that the Rocke and Lorenzato model fits the observed data quite well. The various steps in the computation are displayed in Table 3. Inspection of Table 3 reveals that the estimated AML is 7.276 ppt and this provides a RSD of 7.78%. Note that a wide range of MLs are possible for these data. For example, spiking at 200 ppt the ML is 153 ppt whereas spiking at 10 ppt yields 6.66 ppt. Both spiking concentrations meet USEPA’s 5 : 1 criterion and would therefore represent valid estimates of the ML.

### 5.4 Alternative Formulations

An alternative that departs somewhat from the AML is to estimate the true concentration that leads to a measured RSD of 10% or 20% or whatever is achievable. Requiring 10% will not always lead to a solution since the rate of change in standard deviation relative to concentration may be greater than 0.1. The solution for the case of nonconstant variance Equation (26) involves iterative solution of

\[
y_Q = \frac{1}{r} \sqrt{V(\hat{y}_Q)}
\]

(26)

where \( r \) represents the RSD (e.g. \( r = 0.1 \) for a 10% RSD). The estimate, referred to as \( L_Q \) based on Currie’s “determination limit”, is then Equation (27):

\[
L_Q = \frac{y_Q - b_{0w}}{b_{1w}}
\]

(27)

Note that here, the RSD is of the predicted measured concentration relative to the standard deviation of the predicted measured concentration, which includes uncertainty in the calibration function. In contrast, for the previous estimators, including the AML, the RSD is computed post hoc in terms of true concentration and as such, will generally be somewhat smaller. When applied to the silver data application of Equations (28) and (29) yields \( L_Q = 7.836 \) for an RSD of 10% which is quite similar to the AML.

### 5.5 The Estimator According to Gibbons et al.

Gibbons et al.\(^{(27)}\) have provided a direct estimator of \( L_Q \) under the assumption that square root transformation of both \( x \) and \( y \) homogenizes variance.\(^{(1)}\) This leads (Equation 28) to the predicted concentration \( x^*_a \) for which

\[
\hat{y} = \frac{100}{\alpha} s(\hat{y})
\]

(28)

the predicted response (\( \hat{y} \)) that is \( 100/\alpha \) times its estimated standard deviation (\( s(\hat{y}) \)). Let \( y^*_a \) denote the

![Figure 6](image.png)

**Figure 6** Relationship between concentration and variability – Rocke and Lorenzato Model.
value of \( \hat{y} \) that satisfies Equation (28). Gibbons et al.\textsuperscript{[27]} solved Equation (28) for \( \hat{y} \) and showed that a good approximation can be obtained as (Equation 29)

\[
\hat{y} - \bar{y} = \frac{100}{a} s_{y,x} \approx \hat{y} \quad \text{(29)}
\]

also see Gibbons.\textsuperscript{[11]} Gibbons et al. make several observations regarding this estimator. First, they suggest that with small numbers of measurements, \( s_{y,x} \) may be a poor estimator of the true population standard deviation \( \sigma_{y,x} \) and we may wish to replace \( s_{y,x} \) with its upper confidence limit.

Second, the previous definition of \( a/100 \) times the standard deviation applies to the metric in which the \( L_Q \) is estimated. In the present context, a square-root transformation is used to stabilize variance across the calibration line while preserving linearity of the function. An RSD of 10% in this transformed response metric actually corresponds to a 20% RSD in the raw concentration metric. Therefore, obtaining a 10% RSD in the metric of measured concentrations would require a 5% RSD in the transformed response scale.

Application of this estimator to the silver data yields an \( L_Q \) of 22.159 mg L\(^{-1}\) for a 10% RSD in the transformed metric. This value is somewhat higher than the previous estimators indicating that in this example, the square-root transformation failed to bring about constant variance at the lowest concentrations.

6 DISCUSSION

Perhaps the most significant contribution of this work is to demonstrate that the most critical source of bias in
estimating limits of detection and quantification is the
effect of nonconstant variance. Results presented here
reveal that a myriad of DL estimates can be obtained
from exactly the same data and analytic method solely
as a function of the concentration at which samples
are spiked. The only solution in this case is to base
limits of detection on multiple-concentration calibration
data and either directly model association between
variability and concentration or use a variance-stabilizing
transformation.

In the calibration setting, four general DL estimators
are described and the four methods appear to give
reasonably similar results, at least in the example
considered here. This finding indicates that we pay a
very small price for considerable generality by adopting a
tolerance interval-based approach that will cover 99% of
all future detection decisions compared to only a single
future detection decision. Similar results were found for
calibration-based quantification limit estimators.

Despite the guidance provided by this developing litera-
ture on analytical detection decisions, USEPA continues
to base regulations on the MDL or, for cases in which
quantifiable measurements are required, a simple mul-
tiple of the MDL (i.e. the ML). As illustrated here,
this practice can lead to bias, most notably an extreme
dependence on the selection of spiking concentration.
Despite some guidance on selection of spiking con-
centration, actual practice is guided by demonstrating
compliance with published standards rather than using
the true analytical capabilities of the laboratory. For
example, MDLs are routinely determined in laborato-
ries by spiking as many as 70 constituents at a fixed
concentration in each of seven replicate samples. In
this way it is impossible to iteratively adjust each con-
stituent’s concentration in the way suggested by USEPA.
In contrast, if calibration-based methods were used,
USEPA could designate the range of concentrations
in advance to insure that the computed MDL is not
adversely affected by a poor selection of initial spik-
ing concentration. In future, USEPA should consider
calibration-based approaches for determining limits of
detection and quantification.

**APPENDIX 1**

Details of the WLS prediction interval approach
described by Oppenheimer(23) are provided in the fol-
lowing. To obtain the Hubaux–Vos result set all weights

$$k_i = 1.$$ 
To obtain a DL based on tolerance intervals
see equation 5.3.2 in Gibbons(11) and Zorn, Gibbons and
Sonzogni. (31)

Compute the WLS regression(32) of measured concen-
tration or instrument response \(y\) on true concentration \(x\) for the linear model

$$\hat{y}_w = b_{0w} + b_{1w}x_i $$  \(31\)

where

$$b_{1w} = \frac{\sum_{i=1}^{n} [(x_i - \bar{x}_w)y_i/k_i]}{\sum_{i=1}^{n} [(x_i - \bar{x}_w)^2/k_i]} $$  \(32\)

$$b_{0w} = \bar{y}_w - b_{1w}\bar{x}_w $$  \(33\)
and the weight \( k_i = \frac{s_i^2}{k_i} \) is the variance for sample \( i \) (Equations 31–35). The weighted residual variance is (Equation 36):

\[
\hat{s}_w^2 = \frac{\sum_{i=1}^{n} [(y_i - \hat{y}_w)^2 / k_i]}{n-2}
\]

and the estimated variance for a predicted value \( \hat{y}_{wy} \) is (Equation 37):

\[
V(\hat{y}_{wy}) = s_w^2 \left[ k_j + \frac{1}{\sum_{i=1}^{n} (1/k_i)} + \frac{(x_j - \bar{x}_w)^2}{\sum_{i=1}^{n} [(x_i - \bar{x}_w)^2 / k_i]} \right]
\]

where \( k_j \) is the estimated variance at concentration \( x_j \). An upper \((1-\alpha)100\%\) confidence interval for \( \hat{y}_{wy} \) (i.e. a prediction interval for a new measured concentration or instrument response at true concentration \( x_j \)) is (Equation 38):

\[
\hat{y}_{wy} + t(\sqrt{V(\hat{y}_{wy})})
\]

where \( t \) is the upper \((1-\alpha)100\%\) percentage point of Student’s \( t \) distribution on \( n-2 \) degrees of freedom.\(^{12,18}\)

The WLS estimate of \( L_C \) is therefore (Equation 39):

\[
L_C = \frac{\bar{y}_w}{s_{1w}} s_{L_C}^2 + \frac{1}{\sum_{i=1}^{n} (1/k_i)} + \frac{(L_C - \bar{x}_w)^2}{\sum_{i=1}^{n} [(x_i - \bar{x}_w)^2 / k_i]}
\]

and the WLS estimate of \( L_D \) is (Equation 40):

\[
L_D = L_C + \frac{\bar{y}_w}{s_{1w}} s_{L_D}^2 + \frac{1}{\sum_{i=1}^{n} (1/k_i)} + \frac{(L_D - \bar{x}_w)^2}{\sum_{i=1}^{n} [(x_i - \bar{x}_w)^2 / k_i]}
\]

Note that in order to compute \( L_C \) and \( L_D \) we must have estimates of \( s_{L_C}^2 \) and \( s_{L_D}^2 \) which are often unavailable and must be estimated using a model of standard deviation versus concentration, for example an exponential model\(^{26}\) of the form (Equation 41):

\[
s_e = a_0 e^{a_1 x}
\]

or the model suggested by Rocke and Lorenzato\(^{29}\) which reduces to (Equation 42):

\[
s_e = \sqrt{b_0 + b_1 x^2}
\]

both of which can be fitted by nonlinear least squares and require iterative solution. Gibbons et al.\(^{10}\) suggest a noniterative approximation based on the assumption that variance is proportional to concentration. This assumption leads to the WLS estimates (Equations 43–45):

\[
b_{0w} = \frac{\sum_{i=1}^{n} (y_i/x_i) \sum_{i=1}^{n} x_i - n \sum_{i=1}^{n} y_i}{\sum_{i=1}^{n} (1/x_i) \sum_{i=1}^{n} x_i - n^2}
\]

\[
b_{1w} = \frac{\sum_{i=1}^{n} (y_i/x_i) \sum_{i=1}^{n} y_i - n \sum_{i=1}^{n} (y_i/x_i)}{\sum_{i=1}^{n} (1/x_i) \sum_{i=1}^{n} x_i - n^2}
\]

and

\[
s_w^2 = \frac{\sum_{i=1}^{n} (y_i^2/x_i) - b_0 \sum_{i=1}^{n} (y_i/x_i) - b_1 \sum_{i=1}^{n} y_i}{n-2}
\]

To compute \( L_C \) we can set the weight equal to the lowest nonzero concentration \( x_{min} \) (Equation 46):

\[
L_C = \frac{\bar{y}_w}{s_{1w}} x_{min} + n \left[ \frac{1 + (x_{min} - \bar{x}_w)^2}{n \sum_{i=1}^{n} (x_i - \bar{x}_w)^2} \right]
\]

To compute \( L_D \) we can set the weight equal to \( L_C \) (Equation 47):

\[
L_D = L_C + \frac{\bar{y}_w}{s_{1w}} L_C + n \left[ \frac{1 + (L_C - \bar{x}_w)^2}{n \sum_{i=1}^{n} (x_i - \bar{x}_w)^2} \right]
\]

Given current computing environments, however, there is no reason why the iterative solution should not be performed i.e. simple repeated substitution beginning from \( L_C = 0 \) and \( L_D = L_C \) until convergence (i.e. change of less than \( 10^{-4} \) in estimates of \( L_C \) and \( L_D \) on successive iterations).
REFERENCES

A dioxin-like compound (DLC) is a halogenated aromatic compound that has toxicological properties similar to those of the reference toxicant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). DLCs include other halogenated dibenzo-p-dioxins and dibenzofurans (especially those that are chlorinated in the 2-,3-,7-, and 8-positions, and coplanar polychlorinated biphenyls (PCBs). They associate with the aryl hydrocarbon receptor (AhR) protein, and share some biological end-points with TCDD, notably the induction of Phase I monooxygenase enzymes. Because DLCs normally occur as complex mixtures in environmental and biological samples, it is common to refer to the TCDD equivalent concentration [toxic equivalence (TEQ)], which is obtained by summing for each congeners its actual amount or concentration by an empirical toxic equivalency factor (TEF). Conventional analysis of DLCs by gas chromatography/mass spectrometry (GC/MS) is cumbersome and expensive, and much attention has been given to developing bioassays that will yield a measure of the TEQ in a single determination. Many such bioassays are mechanism-based, meaning that the assay end-point is one of the steps along the pathway of the mechanism of action.

This article begins with an overview of bioassay methods in general, pointing out similarities and differences between chemical assays and bioassays, before describing particular assays that have been developed for DLCs. Among mechanism-based assays, AhR binding assays are well established, and are useful because they include the dioxin-like activity of both productive and unproductive compounds. In assays based subsequent stages of the mechanism of action, unproductive substances can antagonize the responses of productive compounds, a phenomenon that is explicable in terms of target molecule antagonism, in which the AhR protein is the target molecule.

Immunoassays for DLCs have recently received much attention; although their spectrum of cross-reactivity does not always correlate well with TEFs, there has been important recent progress in terms of the sensitivity and detection limit (DL) of these assays. Finally, early life stage bioassays are becoming increasingly important as research has revealed the toxicological effects of DLCs during development.
TEQ will be underestimated if the sample contains DLCs. A unique TEF must be assigned to each DLC, in order to determine how PCBs major contributors to the TEQ of a sample, using the I-TEF scheme.

The standard chemical method of analyzing DLCs is labor intensive, and therefore expensive. After spiking with an isotopically labeled recovery standard such as $[^{13}C_{12}]$TCDD, sample preparation involves solvent extraction and multiple chromatographic procedures to isolate the PCDD/PCDF fraction. Quantitation of individual PCDD and PCDF congeners is achieved by capillary gas chromatography/high-resolution mass spectrometry (MS), giving the concentration of each congener in units such as nanograms of congener per gram of sample.

Chemical analysis cannot provide biological information such as an estimate of a sample’s toxic potency. One such measure, the TEQ, is obtained from analytical data by the use of a TEF, that relates the potency of DLC $X$ to that of the reference toxicant TCDD, whose TEF $= 1$. TEFs are not precisely defined parameters, but are based on a consensus of relative potency, considered over a wide range of end-points and species; the size of the available database varies from congener to congener. The TEQ of a sample is given by

$$\text{TEQ} = \sum \text{concentration of } X \times \text{TEF of } X$$

Figure 1. General chemical structures and numbering system for several DLCs.

### 1.2 Chemical Assay: Toxic Equivalents

The standard chemical method of analyzing DLCs is labor intensive, and therefore expensive. After spiking with an isotopically labeled recovery standard such as $[^{13}C_{12}]$TCDD, sample preparation involves solvent extraction and multiple chromatographic procedures to isolate the PCDD/PCDF fraction. Quantitation of individual PCDD and PCDF congeners is achieved by capillary gas chromatography/high-resolution mass spectrometry (MS), giving the concentration of each congener in units such as nanograms of congener per gram of sample.

Chemical analysis cannot provide biological information such as an estimate of a sample’s toxic potency. One such measure, the TEQ, is obtained from analytical data by the use of a TEF, that relates the potency of DLC $X$ to that of the reference toxicant TCDD, whose TEF $= 1$. TEFs are not precisely defined parameters, but are based on a consensus of relative potency, considered over a wide range of end-points and species; the size of the available database varies from congener to congener. The TEQ of a sample is given by

$$\text{TEQ} = \sum \text{concentration of } X \times \text{TEF of } X$$

In the commonly used I-TEF scheme, TEFs are available for the 17 “most toxic” PCDD and PCDF congeners that are chlorinated in the 2-,3-,7-, and 8-positions, and provisional TEFs have been proposed for the coplanar PCB congeners. The potencies of different DLC congeners vary greatly, as do their relative concentrations in environmental samples. For example, the concentrations of coplanar PCBs in many animal tissues have been found to be orders of magnitude higher than those of PCDD/PCDFs, making the PCBs major contributors to the TEQ of a sample, despite their small TEF values.

The TEQ approach is inherently cumbersome, because a unique TEF must be assigned to each DLC, in order to include its contribution to the calculated potency. The TEQ will be underestimated if the sample contains DLCs for which no TEF has been established, and the more congeners to be assessed, the greater are the complexity of analytical separation and the cost of analysis. Another problem is that the TEQ obtained by GC/MS may not afford an optimal measure of the potency of a sample towards a particular end-point: potency rankings of DLC congeners vary with the end-point and species examined, and not all DLCs produce all end-points. A third problem is that the TEF approach explicitly takes the TEQ of a complex sample to be the sum of the contributions of its components, assuming an additive response to a complex mixture of DLCs (no synergism or antagonism). Putzrath has questioned the assumption of additivity in the TEQ approach from a different perspective. He argues that for parallel log dose–response curves (as is common for DLCs) the relative concentrations of toxicants $X$ and $Y$ needed to produce equal large responses are different from the relative concentrations needed to produce equal small responses. The apparent TEF of a given DLC relative to TCDD will therefore vary according to the position on the dose–response curve, and so considerable inaccuracies might result when TEFs derived from high-dose laboratory studies are used to extrapolate to low-dose environmental exposure.

### 1.3 Bioassays

We define a bioassay as a technique whose end-point is attained through the use of either living organisms or biological materials (e.g. tissues, enzymes, or antibodies). Detection of the end-point signals qualitatively the presence of the analyte, while the intensity of the response is used to quantitate the analyte, as in conventional chemical analysis. In either case, the assay end-point must be calibrated against the concentration of the analyte. In vivo bioassays employ living animals or plants. In vitro methods can utilize living cells, such as bacteria or cultures of animal or plant cells, or they can use isolated tissues, such as liver slices excised from a whole animal. They may also employ subcellular fractions, such as microsomes, chloroplasts, or cytosol, or preparations containing or comprising specific biomolecules such as receptors, enzymes, or nucleic acids. The latter bioassays are hardly different from chemical assays, and many of them use conventional chemical detection techniques such as absorption or fluorescence spectroscopy. One recently developed assay for DLCs, for example, employs the firefly luciferase gene that has been genetically engineered into bacterial and yeast cells (section 2.2.2). In this assay, the measured parameter is light emission catalyzed by luciferase, detected by a photomultiplier tube that records and quantitates light intensity. Likewise, an enzyme-linked immunosorbent assay (ELISA) relies on an enzyme that catalyzes the formation of a product.
that can be quantitated by techniques such as absorption or fluorescence spectroscopy (section 3). The quantity of the product of the enzymatic reaction is proportional to the amount of the antigen–antibody (Ab) complex that was formed.

The cost of analysis generally decreases in the order in vivo assays > in vitro assays with whole cells > in vitro assays with subcellular fractions, but so does the biological relevance of the assay end-point in terms of human health or environmental risk assessment. Animal assays increase in cost with the type of organism (invertebrates < fish < rodents < primates) and with the length of time that is needed for the results to manifest themselves (acute toxicity tests < carcinogenicity tests < multigenerational reproductive tests). Although the use of in vitro assays with bacteria or immortalized cell lines avoids the use of live animals, biological relevance requires some in vivo animal testing when the final objective is human health or environmental risk assessment. Even if an in vivo bioassay replicates the actual toxic end-point, laboratory animals must be used as surrogates when humans are the target organism of concern. Extrapolation of results obtained with laboratory animals to humans is difficult because of the varying susceptibilities of different species and strains towards intoxication by DLCs.\(^8\)

Unlike chemical assays, many bioassays monitor function, and have little or no diagnostic capability for identifying the agent responsible for causing the effect. For example, the acute toxicity of industrial effluents may be monitored by means of the 96 h rainbow trout test or the 24 h *Daphnia magna* test, both of which employ single organisms as surrogates for aquatic species in general. From a regulatory perspective, the lack of diagnostic information is immaterial, since what is required is knowledge of whether or not the effluent is acutely toxic; the identity of the toxicant can be ascertained in a follow-up study, if it is not already known. Other effects such as developmental toxicity in aquatic organisms can also be conveniently studied in this way (see section 4). Similar considerations apply to testing new drugs or pesticides for effects such as carcinogenicity or teratogenicity; in such cases, the identity of the substance is known, and what is required is quantitative information about its possible adverse biological effects.

Bioassays with live organisms or cell cultures, enzyme assays, and immunoassays monitor overt end-points that are different from the end-point of interest to environmental or human health, and a correlation must then be drawn between the surrogate end-point and the end-point of interest. Acute toxicity tests such as the LD\(_{50}\) have often been used, incorrectly, as a measure of the toxic potencies of substances towards chronic exposures. This is particularly inappropriate for DLCs, which cause lethality by mechanisms different from those involved in other end-points.\(^9\)

Many issues concerning the applicability of bioassays are fundamental questions associated with any analytical procedure, such as the shape of the dose–response curve and its limits of quantitation. Consider a generic calibration curve such as that shown in Figure 2. Parameters of analytical importance include its shape (linear or nonlinear) and slope (calibration sensitivity), the range of analyte concentrations over which the calibration curve is valid, reproducibility, and the DL. In chemical analysis, the DL is frequently defined as the response that is three standard deviations away from that of the “blank”.\(^{10}\) The analyte concentration at the DL is given by \(c_{DL} = 3 \times s_{bl}/S\), where \(s_{bl}\) is the standard deviation of the blank and \(S\) is the calibration sensitivity. The ideal analytical procedure has a linear calibration curve over a wide dynamic range and has a large slope, permitting a low DL. The foregoing parameters are mutually dependent: linear responses have inherently wider dynamic ranges than responses whose calibration sensitivities fall progressively with increasing analyte concentration. Low DLs require techniques that have large calibration sensitivities (i.e. a small amount of analyte produces a response that is significantly different from a blank) and/or high precision, implying reproducibility and a small standard deviation of the measurements. Chemical analysts also seek procedures that have high specificity for the analyte of interest, implying no interference by other analytes but, as noted already, this is often not possible with bioassays.

A wide dynamic range is rare with in vitro bioassays, and is impossible for in vivo bioassays, because the response is saturable. In acute lethality or teratogenicity assays, for example, there will be some concentration
of analyte above which essentially all the individuals die or are born with birth defects. Consequently, it is impossible for the response to increase further, and so $S \rightarrow 0$ at high analyte concentration. Moreover, the experimental uncertainties are usually larger than in physical techniques, because of biological variability among individuals in the groups being tested, even when using inbred strains of organisms of the same sex, age, and weight. At the lower limit of quantitation, a relatively high concentration of analyte may be needed to achieve a response (the lowest observed effect level) that differs in a statistically significant way from that of the unexposed group.

A particular difficulty arises with respect to the carcinogenicity of DLCs. TCDD is a weak carcinogen in laboratory animals such as rats$^{11}$ and a disputed human carcinogen.$^{12}$ The linear models for extrapolating cancer incidence from experimentally observable doses to the low doses associated with occupational or environmental exposure assume no threshold for the response.$^{13}$ Regulators may define the dose corresponding to a standard such as one excess cancer in $10^6$ lifetimes [e.g. Sielken$^{16}$], as corresponding to risks that might be acceptable to most members of society. Such a response intensity corresponds to concentrations of DLCs that are far below the lowest observed effect level in a bioassay, and a long extrapolation is inevitable.

The foregoing factors mean that quantitative data can rarely be obtained from in vivo bioassays over a range of more than about one order of magnitude. Calibration curves such as Figure 2 are therefore not generally used to evaluate in vivo bioassays; instead an approach such as the analysis of variance (ANOVA) may often be used to give information about whether the various treatment groups are statistically different from each other and from controls. A more appropriate presentation of the data is a histogram such as Figure 3 rather than the continuous function implied by Figure 2.

Another analytical question is whether an assay affords diagnostic information as well as quantitative information; in other words, whether the parameter being monitored identifies the analyte. Bioassays usually have little diagnostic capability in comparison with chemical methods of analysis such as nuclear magnetic resonance (NMR) and MS, although, as already noted, this may be irrelevant for a functional bioassay.

Important applications for DLC bioassays include environmental remediation programs, which usually require the screening of large numbers of samples to determine which sites require remediation, or to monitor the progress of cleanup. In these samples, the analytes must be extracted from matrices such as soil, sediment, and biota. The extent of pretreatment (cleanup) of the sample that is needed before the assay can be applied is a major consideration, because much of the cost of conventional chemical analysis for DLCs is associated with the lengthy cleanup of the sample prior to analysis by GC/MS. Monitoring or screening assays are of limited use unless a major portion of the cleanup effort can be avoided (e.g. Höckel et al.$^{15}$ Schwirzer et al.$^{16}$ Hu et al.$^{17}$). This issue is often not addressed by the advocates of new bioassays.

Mixtures of compounds present further difficulties in bioassays compared with chemical analysis. A major problem in chemical assays is interference between the responses of different analytes. For example, the mass, infrared (IR), and NMR spectra of mixtures are generally uninterpretable, because the analyist cannot confidently assign the peaks to the correct analytes. This difficulty is overcome by the use of linked methods such as GC/MS that combine the resolving power of chromatography with the diagnostic capability of spectroscopic methods. By contrast, the response in a bioassay is due to the whole sample rather than individual analytes, and the activity can be calibrated against the response of a standard substance. Assays for DLCs are normally calibrated against TCDD, and the response of the sample is reported in TCDD equivalents, i.e. the dose of TCDD that would cause the same response intensity. This approach inherently assumes additive behavior of the mixture’s components, without synergism or antagonism of the biological response. Synergism leads to an overestimation of the concentration of the analyte, but is rarely encountered. Antagonism, which is fairly common, can underestimate the concentration of the analyte to the point of a false negative (the sample mistakenly appears to be uncontaminated).

In vivo antagonism can occur by numerous mechanisms that are difficult to differentiate; the situation in vitro is usually less complicated. A common situation is that the
analyte and the antagonist compete for a limited amount of a target biomolecule, such as a receptor or an enzyme; the analyte is processed and leads to the normal biological response or enzyme product, but the antagonist does not get processed. An agonist is a substance that elicits the toxic or biochemical end-point under study, whereas an antagonist blocks or masks the biological activity of an agonist. When administered on its own, such a substance is better described as unproductive rather than as an antagonist.

Antagonism of this sort (target molecule antagonism) is seen only at high concentrations of analytes (agonist with or without antagonist), at which most of the active sites on the target molecule are occupied. At low total occupancy of the target molecule, the unproductive molecule can occupy vacant target molecules without displacing the agonist, and no inhibition of the assay end-point is seen; conversely, at high total occupancy, the unproductive occupation of target molecules by the antagonist can occur only by displacing the agonist. This phenomenon has been seen in teratogenicity studies in which pregnant mice are administered TCDD, with and without coadministration of PCBs. At high doses of TCDD, coadministration of PCbs antagonizes the teratogenic response, owing to occupation of the AhR target molecule by the nonteratogenic PCBs; antagonism is not seen at low doses of TCDD, at which receptor occupancy is incomplete.

Although a bioassay for DLCs can give a numerical estimation of the TEQ of the sample as a whole, relative to the reference toxicant TCDD, it is unlikely that regulatory decisions could ever be based solely on the results of such assays owing to the lack of diagnostic information about the analyte(s). Lesnik has identified several regulatory issues in the context of using immunoassays, but his comments apply equally to other bioassays. The concerns include extraction efficiency and comparison of assay results with those from previously validated procedures, the occurrence of false negatives and false positives, and cross-reactivity with other analytes. These will be discussed in turn.

**Extraction efficiency** is difficult to monitor even when a recovery standard is used, because this added surrogate may be more easily removed from the matrix than endogenous DLCs. The practice of adding a surrogate, such as $^{[13]C_{12}}$TCDD in chemical analysis by GC/MS, is impractical in bioassays, because the surrogate would itself be a DLC and thus contribute to the assay. In principle, the surrogate could be used in the standard addition mode, but this seems not to have been tried in practice. As for validation against other procedures, few proposed assays for DLCs have been rigorously tested in this way (e.g. Zacharewski et al.). Ideally, the assay should require the minimum of extraction and other work-up, to save on analysis time (for a discussion and example, see Hu et al.).

False negatives and false positives: a major application of dioxin bioassays involves screening samples for activity and determining which are below and which above a consensus cut-off TEQ, so that only those samples assaying above the cut-off are taken to detailed chemical analysis. False positives occur when an interfering, but not dioxin-like, substance can evoke the end-point being monitored; to this extent, false positives make the bioassay conservative because the sample’s contamination is overestimated. False positives increase the number of samples that must be subjected to confirmatory analysis; a high rate of false positives negates the benefit of a low-cost bioassay. False negatives, on the other hand, suggest that contaminated samples are clean; from a regulatory viewpoint, any significant occurrence of false negatives is unacceptable. False negatives are most likely to occur if a relatively nontoxic congener masks or antagonizes the activity of a more potent congener.

Cross-reactivity in bioassays would be a problem if one wished to monitor the concentration of a single DLC (e.g. TCDD). Realistically, bioassays for DLCs will be applied to assessing the TEQ of a sample; cross-reactivity is advantageous if each DLC behaves additively in the assay and if the responses of different DLCs match their TEFs reasonably well. Immunoassays for dioxins in environmental samples exhibit cross-reactivity; it is usually possible to predict the types of structures will cross-react, but the real question is whether the TEQ determined by a particular assay reflects the toxic potency of the sample. Bearing this in mind, we state here our prejudice for mechanism-based bioassays: those that use a point along or minimally divergent from the established metabolic pathway leading to toxicity as the indicator of potency.

1.4 Toxicity and Mechanism of Action of Dioxin-like Compounds

Most of our knowledge of the toxicity of DLCs is based on that of TCDD, which elicits numerous toxic responses. In addition to the widely reported acute lethality, which occurs at very low doses and proceeds via a wasting syndrome, other effects include reduced immunocompetence, hyperplasia, carcinogenicity, developmental toxicity (including teratogenicity and errors in sexual differentiation), and altered porphyrin metabolism. TCDD does not induce all effects in all species, and evidence is lacking that all effects are exhibited by all DLCs (for reviews, see Landers and Bunce; Whitlock; Mukerjee; DeVito and Birnbaum).

The complexity of biological responses to TCDD, and extremely limited knowledge about other DLCs and DLC mixtures, make it difficult to assess the toxic potential of
environmental samples, which usually contain complex mixtures of DLCs. Combustion by-products such as fly ash contain a wide range of PCDDs and PCDFs, while biota such as fish, meat, and milk contain a large number of organochlorines. Among the latter, PCDDs and PCDFs are usually minor constituents in comparison with PCBs, at least some of which are dioxin-like, and organochlorine pesticides such as DDT, that in general are not. Among DLCs, PCDDs, PCDFs, and coplanar PCBs combine toxicity with environmental persistence, and their lack of chemical and metabolic reactivity allows them to bioaccumulate through food webs. Other compounds such as partly methylated PCDDs and PCDFs and the chlorinated azobenzenes are of less concern because they are metabolized more rapidly.

Mechanism-based bioassays utilize current knowledge about the mechanism of action of the toxicant, by exploiting a biochemical event in the mechanism of action as an assay end-point from which to estimate the TEQ. The closer the relationship between the biochemical event being monitored and the toxic end-point of interest, the greater is the biological relevance of the assay. The mechanism of action of TCDD as it is currently known is summarized in Figure 4. As already noted, the behavior of other DLCs is generally assumed to be similar.

**Figure 4** Schematic representation of the mechanism of action of DLCs. A ligand (L) enters the cell and binds to the aryl hydrocarbon receptor ligand binding subunit (ALBS) of the cytosolic AhR. The receptor undergoes transformation/activation, nuclear translocation, and dimerization with the aryl hydrocarbon receptor nuclear translocator protein (ARNT), following which it binds to dioxin response enhancers (DREs), resulting in the induction of cytochrome P450 1A1 and a variety of other proteins. The numbers indicate the stages in this mechanism on which bioassays can be based: (1) receptor–ligand binding; (2) receptor transformation and activation; (3) nuclear translocation; (4) DNA binding; and (5) enzyme induction.

Step 1. TCDD is believed to enter cells by passive diffusion: as a lipophilic substance it has a high affinity for the lipid bilayers constituting the plasma membrane, and bioconcentrates in adipose tissue. The biochemical target of TCDD in vertebrates is the AhR protein, so named because it was first detected as a binding protein for certain aromatic hydrocarbons. Most, if not all, biochemical effects of TCDD are AhR-mediated i.e. association of TCDD with the receptor is a necessary precondition for toxicity. The AhR is an oligomeric ~280 kDa protein complex found in the cytosolic fraction
of tissue preparations. It contains an ALBS with molar mass 90–120 kDa, depending on the species, and a molecule of the 90 kDa heat shock protein (hsp90), which is thought to mask the DNA-binding site and keep the receptor in a conformation that can bind the ligand. Association of the AhR with hsp90 is required to maintain functional signal transduction. The remaining composition of the cytosolic AhR has not been elucidated, but evidence exists that it may contain a molecule of the tyrosine kinase c-src and/or the 38 kDa hepatitis B virus X-associated protein 2 (XAP-2). The susceptibility of animal strains to intoxication by TCDD correlates with the affinity of TCDD for the AhR. In highly susceptible animals such as the C57BL/6 mouse, estimates of the association constant are $>10^{11} \text{M}^{-1}$. Less susceptible strains such as the DBA/2 mouse have a lower affinity form of the AhR. The human form of the AhR also has low affinity for TCDD. Binding affinity to the AhR has long been used to identify substances that might exhibit dioxin-like activity. Numerous correlations, beginning with those published by Poland et al., and continuing with quantitative structure–activity relationship (QSAR) studies through the 1980s, showed an approximate rank ordering between receptor binding affinity and enzymatic activity. The term enhancer reflects the increase in the expression of gene products following exposure to substances such as TCDD. DRE binding with TCDD occurs with high affinity. Several DREs have been identified, and are characterized by similarity of their nucleotide sequences. In vitro binding experiments have been carried out with oligonucleotides containing the consensus sequence.

Steps 4 and 5. The DREs appear to act as genomic switches, initiating the transcription of mRNAs, which in turn yield the appropriate protein gene products. Transcription of CYP 1A1 (cytochrome P-450 1A1 mRNA) begins within a short time of exposure to TCDD, and all necessary components appear to be present constitutively, provided that the cells possess functional AhR and ARNT. The exact mechanism of regulation is not yet completely understood; a very recent suggestion is that the liganded AhR complex activates gene expression of a repressor protein that competes with ALBS for binding ARNT, thereby permitting down-regulation of AhR response subsequent to activation. Past speculation has focused on the induction of a plethora of gene products that lead to different toxicological responses; the only well-characterized pathway, however, is monooxygenase enzyme induction. The recognition of the tyrosine kinase pathway suggests that the latter may be responsible for other biological responses to DLC exposure.

Figure 5 The dimensions of TCDD.
One use of mechanism-based bioassays is to follow a particular DLC stepwise through its mechanism of action to determine whether it acts as an agonist or as an antagonist at each step. Consider the case of two substances that both bind the AhR, only one of which induces CYP 1A1. An agonist not only binds the AhR, but successfully surmounts all subsequent hurdles leading to induction of the enzyme; its antagonist may bind the AhR, thereby reducing the stock of AhR molecules available to bind the agonist, but will not necessarily give a positive result at each subsequent step. The use of a series of assays, step by step in the mechanism, can allow the investigator to probe the exact mechanism of action of such compounds. For example, in the case of AhR binding assays, not all substances that bind to the AhR are necessarily toxic, as is clearly demonstrated by indole-3-carbinol (39,60) and certain nonplanar PCBs such as 2,2',4,4',5,5'-hexachlorobiphenyl (PCB 153). These compounds are active in an AhR binding assays, but do not cause dioxin-like toxicity because they undergo the process of radiolabeled ligand, and measure the concentration of receptor–ligand complex (“total binding”). In the second determination, the experiment is repeated with a large (e.g. 200-fold) excess of unlabeled ligand in addition to the radioligand to measure nonspecific binding. The specific binding is the difference between the two measurements. For the assay to be accurate the ligands must be present in excess over the saturable sites (at the highest concentrations) but not in excess over the nonspecific sites.

Saturation assays involving radioligands are usually analyzed by the method of Scatchard, which assumes that the concentration of unliganded receptor (R) is at all times represented by the difference between the initial, total receptor concentration (R0) and the concentration of specifically bound receptor–ligand complex (RL) [Equation 1]:

\[
[R] = [R]_0 - [RL]
\]  

(1)

Under these conditions, Equation (2) gives the relationship between \(K_d\), the dissociation constant of the receptor–ligand complex, and the concentration of the radioligand (L):

\[
\frac{[RL]}{[L]} = \frac{[R]_0}{K_d} - \frac{[RL]}{K_d}
\]  

(2)

From a plot of \([RL]/[L]\) vs \([RL]\), the slope gives \(K_d\) and the intercept affords the total concentration of specific binding sites.

Unfortunately, the Scatchard method is inapplicable to the AhR assay under most conditions, because the unliganded receptor is very susceptible to thermal inactivation of its binding capability. This means that \([R] < ([R]_0 - [RL])\) and, as a result, \(K_d\) is overestimated, often by several orders of magnitude. Previous experiments in our laboratory (38) have shown that it is possible to estimate \(K_d\) from kinetic experiments, even in the presence of thermal inactivation of the receptor. The method is, however, cumbersome and inaccurate, because the rate constants for both receptor–ligand association and complex dissociation must be fitted to the time course of complex formation.

The whole-cell binding assay reported by Dold and Greenlee (65) has been developed to screen cell culture lines for their AhR content, rather than screening different samples for their DLC content. In this assay, the cells are incubated with radiolabeled TCDD (with...
and without unlabeled competitor), and after appropriate manipulations the cells are counted for their radioactivity. Uptake of radioligand is observed only for cell lines having a functional high-affinity AhR.

2.1.2 Competition Assays

Competitive binding assays involve incubating the receptor preparation with a mixture of ligands, one of which is radioactive (the reference radioligand, usually [3H]TCDD in studies involving DLCs). The reference radioligand should bind more avidly than the unlabeled competitor(s) and be present in sufficient concentration to saturate the receptor’s binding sites. In the absence of any competitor, the maximum concentration of specifically bound receptor–ligand complex is formed; increasing the concentration of competitor, at a fixed concentration of the reference radioligand, reduces the level of bound radioactivity, ultimately to near zero. The usual objective is to determine the EC50, the concentration of competitor that displaces 50% of the radioligand. At the EC50, the radioligand and the competitor have equal occupancies of the AhR, and so their RBAs are in the ratio of their concentrations. Alternatively, binding ligands might be distinguished from nonbinding ligands by selecting a cut-off RBA as the limit of a positive response. For example, suppose that TCDD is the reference radioligand and that 10^{-5} is the cut-off RBA. For a concentration of radiolabeled TCDD of 1 nM (a reasonable value), a series of commercial chemicals to be tested could be prepared at 100 µM. The RBA will be <10^{-5} if the bound radioactivity for radioligand + competitor is >50% of that for the radioligand alone. Relative EC50s may reflect kinetic affinities or equilibrium affinities, depending on whether the association between receptor and ligands is freely reversible.

The common graphical presentation of a competition assay is a sigmoidal curve of percent specific binding vs log (competitor concentration). The EC50 may be obtained either graphically (Figure 6) or, better, using a statistical technique such as the probit or logit method. We have stressed elsewhere that the statistical uncertainty in the EC50 will be high unless a large number of competitor concentrations is used to define the sigmoidal curve. Care must be used in interpreting the sigmoidal curve, because of the incorrect impression that at low ligand concentrations there is a threshold below which the level of specific binding (and by implication the toxic potency) of the DLC is insignificant. This is an artifact of using a logarithmic concentration scale (Figure 7a and b).

An advantage of the competitive method is that more than one unlabeled competitor can be present; an occupation ratio is established for the specific binding sites on the receptor, based on the relative concentrations and affinities of all the competitors. For a given competitor,
or mixture of competitors, the EC_{50} value is by definition equivalent to the concentration of the reference radioligand. In the case of the AhR, with 1.0 nM [^{3}H]TCDD as the reference radioligand, whatever the actual concentration of the competitor(s) at the EC_{50}, this will occupy the same fraction of the receptors as 1.0 nM TCDD. Therefore, a measure of the TEQ is obtained from a single experiment.

An important check on this methodology is to use the unlabeled form of the reference radioligand as the unlabeled competitor; the EC_{50} value for the unlabeled ligand should equal the concentration of the reference radioligand. In consequence, the EC_{50} concentration obtained from a competition experiment depends upon the concentration of the reference radioligand; therefore in comparing literature values of EC_{50} s one must take care to note the concentration of the reference radioligand. RBAs, however, are independent of the concentration of the reference radioligand.

In the analysis of an extract from an environmental matrix, the analyst prepares a series of dilutions of the initial extract and plots dilution (abscissa) vs bound radioactivity (ordinate). Aliquots of these solutions are incubated at a fixed temperature for a predetermined time with fixed concentrations of the AhR preparation and the reference radioligand. The bound radioactivity is conveniently expressed as the percentage of the maximum specific binding (%SB) obtained with the reference radioligand in the absence of competitor. The %SB is determined for each dilution, from which one can estimate the extent by which the initial extract must be diluted to produce 50% of the maximum specific binding. At this dilution of the environmental extract, the DLs in the extract occupy half the receptor or other recognition sites (EC_{50}); the TEQ of the sample is then equal to the TEQ of the reference radioligand, from which one can work back to the concentration in the undiluted sample.

A complication for interpreting RBAs, whether they represent kinetic or equilibrium affinities, is that the receptor–ligand complex may be untransformed, partly transformed, or wholly transformed, depending on the conditions of the experiment and the source of the AhR. This issue was not appreciated before transformation was recognized as a step in the mechanism of toxic action of TCDD. One clear-cut study is that of Bradfield et al. using mouse hepatic AhR at 4°C; their results refer to equilibrium, because mouse hepatic AhR neither inactivates nor transforms at a significant rate at this temperature, and so the Scatchard method of analysis is justified. In contrast, it is likely that most studies involving rat hepatic receptor near room temperature have been conducted under thermally inactivating, and hence kinetic, conditions.

Competition assays all suffer from the disadvantage that the signal (in this case, the intensity of radioactivity) is maximum when there is zero competitor and declines asymptotically towards zero as the concentration of the competitor increases. The DL for the competition assay is therefore difficult to define. Schneider et al. took a 20% reduction in specifically bound radioactivity to be distinguishable from the 100% level, which is equivalent saying that the TEQ of the unlabeled competitor must be at least 25% that of the reference radioligand. For 1 nM [^{3}H]TCDD, this corresponds to 0.25 nM TEQ. A typical experimental protocol employs 10-μL aliquots of competitor solution in a final 1 mL of incubation mixture, so the DL is 250 fmol TEQ per incubation mixture.

It is difficult to account for nonspecific binding quantitatively in a competition assay, unlike a saturation assay (see above). The usual approach is to determine nonspecific binding under conditions that no unlabeled competitor is present, and to assume constant nonspecific binding for the entire series of dilutions of the unlabeled competitor.

The competition assay was first applied to the analysis of environmental samples by Hutzinger et al. Municipal fly ash was analyzed by incubating a fixed amount of [^{3}H]TCDD and a fixed amount of rat hepatic cytosol (containing AhR) with increasing amounts of an extract prepared from the fly ash at 0–5°C. The amount of bound radioactivity was determined by sucrose density gradient centrifugation analysis (SDGC) (see Tsui and Okey). This method involved treating the incubated mixture with dextran-coated charcoal to remove unbound and loosely bound radioligand, separating an aliquot by SDGC, collecting the fractions, and assaying each for its radioactivity, a very time-consuming procedure. The DL was in the range 100–200 pg of unlabeled TCDD. The authors recognized that the assay “assesses the total biologic activity of the PCDDs/PCDFs in a sample and does not focus on only one specific congener”, and also that the DL of any such competition assay would be lower the higher is the specific activity of the radioligand. The method was later extended to a range of individual PCDDs and their brominated analogs and to the analysis of 3,3',4,4'-tetrachloroazobenzene (TCAB) in a series of chloroaniline-based herbicides. In these last two reports the receptor–ligand binding assay was compared with aryl hydrocarbon hydroxylase (AHH) induction; for PCDD, PCDF, and PCB analytes, the sensitivities of the two assays were similar, but with TCAB the receptor-binding assay was much more sensitive than AHH induction, probably because TCAB is more readily metabolized.

Bradfield and Poland made several modifications to the receptor–ligand binding assay. Their approach differed from that of Hutzinger et al. in the following
respects: (1) the reference radioligand was $^{125}$I-2-iodo-7,8-dibromodibenzo-p-dioxin, which can be obtained at much higher specific activity than $^3$H]TCDD, permitting lower DLs to be achieved (3 pg of unlabeled TCDD); (2) they carried out the assay by removing excess ligands from the incubation mixture with dextran-coated charcoal followed by $\gamma$-counting, without using SDGC; (3) they used heparic cytosol from the C57BL/6 mouse rather than the rat, having found that the mouse receptor is thermally more stable with respect to loss of binding ability; (37) and (4) they used a 16-h incubation at 4°C. The assay was applied to a series of halogenated dibenzo-p-dioxins and dibenzofurans, with the recognition that other DLCs could in principle be analytes for the method. Besides its higher specific activity, 2-$^{125}$I-iodo-7,8-dibromodibenzo-p-dioxin is a good choice as the reference radioligand because it binds to the AhR almost as strongly as TCDD [cf. Goldstein and Barrett (86)]. Its disadvantage is its relatively short half-life of 60 days, which necessitates resynthesizing the ligand fairly frequently, compared with a tritiated ligand whose radiochemical half-life is 12.3 years.

The introduction of the hydroxyapatite (HAP) assay (80) greatly improved the convenience of the receptor–ligand binding technique. In this assay, proteins in the incubated mixture are adsorbed on HAP, excess loosely bound ligands are removed using buffer containing a mild detergent (Triton X-100), and the radioactivity is counted after suspending the protein–HAP pellet in scintillation fluid. Using $^3$H]TCDD as the reference radioligand, the HAP version of the receptor–ligand assay was shown to be applicable to a range of substituted azobenzenes (81) and chlorinated stilbenes (82) in addition to PCDDs, PCDFs, and PCBs. Chlorinated stilbenes were unusual in that both AhR binding affinity and the induction of monoxygenase enzyme activity in rat H4IIE hepatoma cells showed no obvious dependence on ligand structure. The HAP assay is inapplicable, however, to AhRs that bind only weakly to DLCs, for example the human AhR, because the detergent washing step strips the DLCs from the receptor (83).

Schneider et al. (69) carried out a detailed examination of parameters such as incubation time for a successful AhR ligand binding assay. Using $^3$H]TCDD as the radioligand, C57BL/6 mouse cytosol as the source of AhR, and 25°C as the incubation temperature, they showed that mixtures of ligands of widely varying structure behaved additively with respect to receptor binding activity, once their concentrations were expressed in terms of TCDD equivalents. In common with previous workers they found that RBAs varied in the order PCDDs > coplanar PCBs > nonplanar PCBs [but note that low RBA towards the AhR does not absolve nonplanar PCBs of suspicion of non-AhR-mediated toxic effects (84)]. It is important to add the cytosol preparation to the premixed ligands; if the ligands are added sequentially, the first ligand added occupies a disproportionate fraction of AhR binding sites (67,69). This observation indicates that association between the ligand and the AhR is essentially irreversible at this temperature, signifying that most of the ligand–AhR complex had already undergone transformation by the time it was analyzed, so that RBAs determined under these conditions represent kinetic rather than equilibrium affinities for the AhR.

Huang et al. (17) compared the HAP AhR ligand binding assay and chemical analysis by GC/MS for the analysis of DLCs in environmental matrices, with emphasis on how the results were affected by the extent of sample cleanup. Matrices analyzed included fly ash, fish tissue, soil, pulp-mill sludge, and petrochemical catalyst wash water. Fish tissue and contaminated soil required extensive cleanup before meaningful assay results could be obtained. The bioassay was considered conservative in that the apparent TEQ detected was always as great as (and often much greater than) that found by GC/MS, even after including the contributions of coplanar PCBs. Further analysis by GC/MS identified much of the missing material as PAHs, which also bind to the AhR but which do not evoke dioxin-like toxicity. Although AhR binding assays can be used to screen unknown environmental samples for possible DLC contamination, they cannot provide quantitative information unless interfering analytes have been shown separately to be absent. In appropriate situations they would be useful for monitoring the progress of an environmental remediation program fairly rapidly and inexpensively, always remembering that AhR binding assays do not provide chemical identification of what actually binds the AhR and also that agonists and antagonist both give a positive response. In addition, the observed radiation intensity does not depend linearly upon sample TEQ. It approaches zero asymptotically when the TEQ of the sample greatly exceeds that of the radioligand, and so a series of serially diluted samples must be assayed in order to establish the numerical factor by which the original extract must be diluted in order to reach the EC$_{50}$. 

Rao and Unger (85) suggested using the AhR affinities of different ligands to estimate risk of exposure to mixtures of congeners. Competitive affinities of the DLCs for rat AhR were used to estimate the fraction of each DLC congener in human adipose tissue that would be bound to AhR. Drawbacks to this approach include the need for congener-specific analysis, and assumptions about the equivalence of human and rodent AhR towards different DLCs, equivalence among DLCs with respect to bioavailability, and whether receptor occupancy is a sufficient criterion for toxicity. Among these factors, that
of equivalency of human and rodent AhRs is especially suspect, because they differ substantially in their thermal stability in vitro\(^ {22}\) and their affinity towards TCDD \(^ {24, 40}\).

### 2.2 Post-transformation Assays

This group of assays includes tests for the production of the transformed AhR–ligand complex and the production of nuclear AhR–ligand complexes, and downstream end-points such as monooxygenase enzyme induction and reporter gene assays in which the reporter gene product is under the control of a DRE. Transformation in vitro is temperature dependent; its rate varies with species (guinea pig > rat > human)\(^ {73, 86}\). Transformation is accompanied by an increase in the strength of ligand binding\(^ {51}\) and can be monitored by following the loss of the ligand’s ability to dissociate from the complex.\(^ {67}\) Other parameters that are altered by transformation are the change of molecular mass of the AhR resulting from the dissociation of protein subunits\(^ {87}\) and the properties of the dissociated subunits, such as the binding affinity of ALBS–ARNT to DNA\(^ {73, 88}\) and the phosphorylating ability of c-src.\(^ {35}\) Transformation is difficult to follow because no simple methods yet exist to demonstrate the production of specifically the transformed or the untransformed TCDD–AhR complex, or to show that one of them has been produced to the exclusion of the other.

Petrulis and Bunce\(^ {89}\) studied the first step beyond ligand binding in experiments in which competing ligands were added sequentially to hepatic cytosol. At low temperature (0–4°C), transformation is sufficiently slow in some species that the reversibly formed AhR–ligand complex can be distinguished from the transformed AhR in which the ligand is essentially irreversibly bound. Provided that binding occurs at all, even weakly binding ligands such as PCB 153 appear to induce transformation as effectively as TCDD. This was taken as evidence that the antagonism of TCDD-induced end-points by PCB 153 does not occur at the stage of dissociation of the multimeric AhR complex.

#### 2.2.1 Gel Retardation Assay

The gel retardation assay can be used to show binding to a synthetic oligonucleotide containing the DRE consensus sequence. In this method, \(^ {32}\)P]adenosine triphosphate (ATP) is used to phosphorylate the oligonucleotide, which is then allowed to bind to a deficit of cytosolic AhR–ligand complex. The bound and unbound oligonucleotides are separated by nondenaturing polyacrylamide gel electrophoresis. Binding to the protein reduces the charge-to-mass ratio of the oligonucleotide, and it runs more slowly through the gel, hence the name gel retardation analysis. The retarded and unretarded bands are visualized using autoradiography (Figure 8). A key advantage of this technique is that it does not require a radiolabeled ligand, as it is the oligonucleotide that is labeled. It can therefore be applied to any AhR-binding compound.

Safe’s group studied the production of the nuclear complex by incubating radioligand with AhR and monitoring the accumulation of radioactivity in the nucleus.\(^ {91, 92}\) The rates of transformation of the AhR–ligand complexes were parallel when two end-points were compared: translocation to the nucleus and formation of a shifted band in the gel retardation assay.\(^ {93}\) In principle, formation of the nuclear AhR–ligand complex could be used as an environmental assay, although a competition assay would be required to monitor an environmental sample because the latter is unlabeled. As with receptor binding, the experiment would consist of measuring the reduction in bound radioactivity when the environmental sample was incubated with a fixed aliquot of receptor and a fixed aliquot of radioligand.

Santostefano et al.\(^ {94}\) attempted to use the gel retardation assay to examine the relative potencies for AhR activation of different ligands. By the use of Woolf plots, they found that transformed complexes of the rat AhR with different ligands had similar affinities for oligo-DRE. Equilibrium binding between AhR–ligand complex and the oligo-DRE was demonstrated by showing that unlabeled DRE added later could displace the \(^ {32}\)P-labeled DRE from the AhR–ligand complexes. Ligands such as 1,2,7,8-tetrachlorodibenzo-furan (TCDF), which binds weakly to rat AhR, produced less transformed AhR complex; this was proposed to be due to inactivation of the unliganded AhR competitively with binding. In principle, an assay for environmental samples could be developed.
using a fixed amount of AhR, followed by incubation with a fixed amount of DRE to probe the environmental samples’ ability to transform the AhR.

Petrulis and Bunce\(^{(61)}\) studied the relative transforming ability of AhR ligands both singly and in combination, using cytosolic extracts from rat and guinea pig. Neglecting minor interspecies difference, ligands with high affinity for AhR [TCDD, 3-MC and 3,3',4,4',5-tetrachlorobiphenyl (PCB 77)] all produced comparable intensities of the shifted band upon gel electrophoresis. Weakly binding ligands such as PCB 153 and 2,3,3',4,4',5-hexachlorobiphenyl (PCB 156) gave only limited intensities of the shifted band. Combinations of productive ligands (those that exhibit high affinity for AhR and high potency) at saturating concentrations yielded intensities similar to those resulting from a single high-affinity ligand; unproductive ligands at high concentration out-competed lower concentrations of productive ligands. This behavior shows clearly that the mechanism of action of the unproductive ligands diverges at or before the DRE binding step in the mechanism, and that target molecule antagonism is a plausible explanation for the antagonism of the toxicity of productive ligands by unproductive ligands. At high total receptor occupancy, the ligands compete for a limited amount of the target molecule AhR, whereas at low total receptor occupancy, AhR sites are plentiful for occupancy by both ligands.

The biological relevance of the gel retardation assay may be limited because it employs an oligonucleotide which is only a short DNA fragment, precluding the possibility of reproducing multiple DRE occupancy which may be associated with toxicity in actual organisms. Although binding to native DREs occurs only after the AhR–ligand complex has dimerized with ARNT,\(^{(55)}\) in vitro experiments with oligonucleotides are carried out without adding ARNT. It is not clear whether the in vitro system does not require ARNT or whether sufficient ARNT is present in broken-cell preparations of cytosol.

A current point of interest is whether antagonistic ligands that bind AhR fail to undergo transformation. Petrulis and Bunce\(^{(61)}\) indicate that unproductive ligands such as PCB 153 induce dissociation of liganded AhR complexes as effectively as TCDD, but bind much less strongly to synthetic oligonucleotide. This phenomenon may also be species-dependent, since α-naphthoflavone–AhR complexes transformed much more efficiently (judged by gel retardation assays) when guinea pig was the source of cytosolic AhR compared with rat.\(^{(94,95)}\) The possibility that mechanism-based bioassays may give species-dependent results led Denison et al.\(^{(56)}\) to suggest that bioassays should be run in multiple species to assess toxic potency thoroughly, but that is impractical if the goal of bioassays is to achieve high throughput and low cost. The alternative might be to standardize the strain of animal or the cell line that is to be used in the assay, but at the risk of overlooking some of the DLCs present in environmental samples.

Other possible assays that could be devised include one based on detecting the formation of the ALBS–ARNT heterodimer, possibly using an Ab-based method. This would require an Ab that could recognize the ligand-bound ALBS–ARNT complex, rather than the individual components, and may not be practical. An assay could also be imagined in which the formation of the mRNAs following transcriptional activation was monitored, but this does not yet seem to have been attempted.

With respect to cancer as a toxic end-point, Büsser and Lutz\(^{(97)}\) investigated an assay based on the ability of hepatocarcinogens, including TCDD, to stimulate unscheduled DNA synthesis. The protocol involved oral administration of the test substances to rats or mice, followed 24 h later by radiolabeled thymidine. Four hours later the animals were killed and the extent of radiothymidine incorporation into hepatic DNA was measured in comparison with untreated controls. The female rat and male mouse (but not male rat) showed increased DNA synthesis at TCDD exposure levels of 1–2 nmol kg\(^{-1}\). The procedure is relatively fast, but a screening program would require large numbers of animals, in addition to which, no information is yet available about the responsiveness of other DLCs in the assay.

### 2.2.2 Reporter Gene Assays

Reporter genes are DNA sequences that encode for proteins or enzymes with characteristic activities that are unique to the cells used for the test and that are easily measured using conventional biochemical assays. As noted by Lewis et al.,\(^{(98)}\) reporter genes were first employed for studying the mechanisms of transcriptional activation in cells, but have now become valuable tools in bioassay systems. Techniques are now available for transfecting new genetic material into the host cells so that the change is heritable over the long term (stable transfection), although the selection of the stable transfecants is very time consuming.\(^{(99)}\) The alternative, transient transfection, does not provide indefinite stability, but allows more copies of the foreign DNA to be introduced into the host cell; transient transfection must always be used when the host cells are primary cultures, which are inherently viable only for short periods.

An early reporter gene to be developed was chloramphenicol acetyl transferase (CAT), an enzyme from E. coli that is foreign to eukaryotic cells. It is assayed by quantitating the acetylation products of the antibiotic chloramphenicol; the method carries an internal check...
because only the cells that remain transfected survive in the presence of the antibiotic. The original CAT methods required the use of either radiolabeled chloramphenicol or radiolabeled acetyl coenzyme A in order to assay the enzyme product; more recently, fluorescent chloramphenicol derivatives have been developed to allow fluorescence as the assay method.\(^{99}\) Many cell lines used for bioassays today are transfected with CAT or another antibiotic-resistance gene, in addition to the reporter gene whose gene product is the primary objective of the method. The antibiotic-resistance gene is present to monitor that the cells, which are grown in a medium supplemented with the antibiotic, retain their viability, and so that contaminant microorganisms will not survive.

In the context of analysis for DLCs, assay methods so far developed involve introducing DNA that encodes for an abnormal response into cells that already contain functional AhR machinery, usually immortal hepatoma cells. The foreign DNA is introduced downstream from the DRE; ligand binding followed by interaction with the DRE causes the translation of the reporter gene product in the bioengineered cells. Reporter gene assays require the DLC to undergo three stages in the mechanism of toxic action (ligand binding, transformation, and DRE binding) in order to observe a positive response; as such, they are not strictly receptor–ligand binding assays.

El-Fouly et al.\(^{100}\) first reported linking AhR binding to the expression of an easily monitored gene product through the use of recombinant cell lines. They constructed, in AhR-containing mouse hepatoma cell lines, a stable recombinant vector that expressed human placental alkaline phosphatase (AP) under the control of a section of CYP 1A1 promoter that contains several DREs. Exposure to TCDD led to receptor binding, transformation, DRE binding, and dose-dependent expression of AP. The significance of the use of human placental AP is that this particular enzyme is unusually stable to heat. Other native phosphatases can be thermally denatured before monitoring the culture’s phosphatase activity by measuring the rate of hydrolysis of \(p\)-nitrophenyl phosphate (a substrate for the enzyme) to \(p\)-nitrophenolate anion, which is easily monitored spectrophotically. In the presence of TCDD, AP activity was induced in a saturable, dose-dependent manner (ED\(_{50} \approx 0.3 \text{nM}\)). Other DLCs, including TCDF, 3-MC, PCB 77, and 3,3',4,4',5-pentachlorobiphenyl (PCB 126) (but not PCB 153) also induced near-saturating levels of AP activity. The rate of production of \(p\)-nitrophenolate was taken to be proportional to receptor occupancy by DLCs, although this implies the questionable assumption that all DLCs undergo stages subsequent to AhR binding with equal efficiency.

Several groups have recently introduced elegant variants of the AhR reporter gene assay in which AhR binding has been linked to activation of the LUC gene, which encodes for luciferase, the enzyme that is responsible for light emission in the common firefly. The significance of this technique is that the experimentally observed parameter is light intensity, which can be monitored easily and with high precision using a luminometer. Balaguer et al.\(^{101}\) transiently transfected the luciferase reporter gene into Hepa 1c1c7 cells so that the luciferase gene was under the control of DREs. Ligand binding, followed by transformation and DRE binding, led to the translation of luciferase gene, leading to the dose-dependent emission of light when luciferin was added. This system was able to assay for TCDD itself, and for TCDD-like activity in black liquor from pulp and paper mills.

Murk et al.\(^{102}\) obtained stable transfectants of the luciferase reporter gene in rat hepatoma H4IE cells, and were able to analyze both reference compounds and PCB mixtures by means of this assay, which they termed chemically activated luciferase gene expression (CALUX). The reaction was carried out in 24-well plates, and with TCDD as a reference, the EC\(_{50}\) was reached at 10 pM. The DL, defined as three times the standard deviation of the DMSO blank, corresponded to only 0.5 fmol of TCDD per well. The maximum light emission, however, differed among analytes, presumably reflecting differences in the efficiency of events subsequent to AhR binding (transformation and/or nuclear translocation and/or DRE binding). The assay was applicable to both single DLCs and environmental samples, including sediment porewater\(^{102}\) and blood plasma,\(^{103}\) and it was suggested that the CALUX assay would provide a rapid and relatively noninvasive test for exposure to DLCs in wild-life. The same group has also developed a trout hepatoma cell line with the luciferase reporter gene; luminescence was measured by lysing the cells after 4 days of exposure to the DLC and adding standard luciferin reagents. TCDD had an EC\(_{50}\) for light emission of 0.06 nM (maximum intensity 100%, assumed): 1,2,3,7,8-pentachlorodibenzo-p-dioxin, 2,3,4,7,8-pentachlorodibenzofuran, PCB 126 and PCB 77 had EC\(_{50}\) (maximum intensity) 0.3 nM (120%), 0.2 nM (114%), 10 nM (110%), and 11 nM (43%), respectively. 2,3,3',4,4'-pentachlorobiphenyl (PCB 105) and 2,3',4,4,5'-pentachlorobiphenyl (PCB 118) were unresponsive in the assay.\(^{104}\)

The CALUX system and the related P450 reporter gene system (P450RGS) have been commercialized by contract analytical laboratories. P450RGS utilizes human HepG2 hepatoma cells modified by the introduction of the luciferase gene. The P450RGS assay screens for a wide variety of planar aromatic xenobiotics,\(^{92}\) prospectively allowing those environmental samples of the greatest potential concern to be identified for more detailed testing. PAHs are more responsive at short incubation times (6 h) and DLCs at longer times (16 h). The
relative light emission varied significantly among DLCs (TCDD, 27-fold induction; PCB 77, 15-fold; 2,3,4,5,5,6-pentachlorobiphenyl (PCB 114), 19-fold; PCB 126, 111-fold; PCB 156, 6-fold; 3,3',4,4',5,5'-hexachlorobiphenyl (PCB 169), 29-fold), but it is not clear from the reported data whether these represent saturated responses. TEFs calculated from the P450RGS system were substantially different from the consensus values. Although the P450RGS assay has been applied to the determination of the TEQ of environmental samples, it does not yet appear to have been established that mixtures of DLCs or PAHs respond additively in the assay. Consequently, TEFs obtained in the assay must so far be considered to be only semiquantitative.

The development of reporter gene assays is clearly more demanding than conventional ligand binding assays, but the potential payoff is a simpler assay protocol. The limitation of conventional saturation assays to radiolabeled ligands is overcome by using reporter gene assays, because the assay end-point is the phenomenon under the control of the reporter gene, such as light emission from luciferase. Reporter gene assays are always carried out as saturation assays, because all competitors for the same AhR binding sites act as potential agonists for the reporter gene. The data cited above make it clear, however, that the intensity of light emission from different ligands is not necessarily equal even under conditions of saturation of AhR binding sites. This is consistent with unequal transforming or DRE binding ability of different DLCs. Experiments with 2,2',5,5'-tetrachlorobiphenyl (PCB 52) in the recombinant assay involving firefly luciferase as the reporter gene product indicate that the extent of DRE activation by less productive DLCs is also cell-line dependent.

2.2.3 Enzyme Induction Assays

Several assays have been developed in which the induction of a particular gene product has been monitored in vivo or in cell culture following exposure to TCDD. The most common end-point is the induction of a monooxygenase activity such as AHH or 7-ethoxyresorufin-O-deethylase (EROD). These are markers for the CYP 1A1 gene product (cytochrome P450 1A1), which is the principal form of cytochrome P450 induced by TCDD and PAHs such as 3-MC. CYP 1A2 is inducible by nonplanar PCB congeners and also by TCDD; its activity can be monitored by following the marker enzyme acetanilide-4-hydroxylase. In addition, 7-pentoxyresorufin-O-deethylase (PROD) is a marker for the phenobarbital-inducible CYP 2B family of cytochrome P450s and 7-ethoxycoumarin-O-deethylase (ECOD) is a marker for both phenobarbital- and TCDD-type inducers. All of these enzyme assays have some degree of cross-reactivity among substrates; no substrate is known that has complete specificity for a single monooxygenase isozyme [reviewed by Hu and Bunce]. Unlike the usual method of carrying out enzyme kinetics which employs constant enzyme and variable substrate concentrations, these assays employ a constant concentration of substrate that is optimized so that the reaction rate \( V \approx V_{\text{max}} \). Under these conditions the rate of product formation is proportional to the enzyme concentration.

The usual protocols for the AHH induction assay involve incubating a preparation of lysed induced cells (and uninduced controls) with a standard solution of benzo[a]pyrene and reduced nicotinamide adenine dinucleotide (NADPH) in the presence of oxygen. The reaction involves the hydroxylation of benzo[a]pyrene, one of whose products, 3-hydroxybenzo[a]pyrene, is monitored by its characteristic fluorescence at 522 nm. AHH activity is reported as picomoles of 3-hydroxybenzo[a]pyrene equivalents formed per unit time per milligram of total protein. Studies of AHH activity frequently employ the rat hepatoma cell line H4IIE, which has low basal activity, but whose activity is readily induced by 3-MC and TCDD. The protocol was refined by Sawyer and Safe as a rapid screening tool for the detection of planar halogenated aromatic compounds. The EROD assay is carried out in a similar fashion in which the lysed cells are incubated with NADPH and 7-ethoxyresorufin, and the reaction is followed by monitoring the fluorescence of the product resorufin at 582 nm. The assay results are reported as picomoles of resorufin formed per unit time per milligram of total protein. The EROD assay is greatly preferred over AHH, because it avoids the use of the highly carcinogenic benzo[a]pyrene.

A key advantage of the AHH and EROD assays is that the parameter detected is fluorescent light intensity, which allows the possibility of low DLs, automation and easy data handling. The protocol for the analysis of unknowns involves preparing a calibration curve of fluorescence intensity vs TCDD concentration and reading the TCDD equivalent of the unknown directly from the curve. The introduction of fluorescence plate readers has permitted EROD assay to be carried out in 48- or 96-well plates.

Both AHH and EROD assays can be carried out using animal tissue or, more commonly, with cells in culture. When whole animals are used, the CYP 1A activity of microsomal preparations of the livers of killed animals is compared with that of hepatic microsomes from control (unexposed) animals. Examples include the work of Parrott et al. on the accumulation of PCDDs in rainbow trout and of Diliberto et al. on tissue distributions of TCDD in mice. Machala et al. used chick hepatocytes for EROD analysis, with injection of
test substances on day 14 of incubation and killing and removal of the livers 24 h later. The assay was applied to eggs treated with individual DLCs but not to mixtures or environmental samples.

The rat hepatoma cell line H4IIE has been extensively used as a convenient standard procedure for assaying environmental samples using cell cultures. Many other hepatoma lines, from humans, rodents, and fish, have also been developed. Primary cultures of hepatocytes are readily prepared, allow the examination of any species of interest, and, it has been argued, are more representative of the metabolism of the normal animal than immortal cell lines.

Because enzyme assay activities are reported in units such as femtomoles per minute per milligram of protein, the total protein content of the biological preparation must be measured. This is usually done using either the method of Lowry et al.[127] or Bradford;[128] more recently, Lorenzen and Kennedy[129] introduced a method based on fluorescamine association that can be carried out by fluorescence assay in the same 96-well plates that are used for EROD analysis.

TEQ values are estimated from enzyme induction experiments by preparing a calibration curve of enzyme activity vs dose of TCDD incubated with the cells. The ability of the environmental sample to induce AHH or EROD is then compared with the dose of TCDD needed to induce the enzyme to the same extent. With respect to DL, the EROD assay is able to detect low concentrations (typically <10 pmol L⁻¹), because fluorescence is the experimentally observed parameter.

Monooxygenase enzyme induction is regarded as a normal, adaptive metabolic response to exposure to AhR-binding xenobiotics rather than a toxic response[130,131] [although recent work suggests that the induction of CYP 1A1 by TCDD causes oxidative damage to DNA].[132] The justification for using enzyme assays to estimate TEQs is the well-established rank-order correlation among DLCs between the doses required for enzyme induction in cell culture and in vivo effects such as thymic atrophy and body weight loss in whole animals.[47,133] In common with overtly toxic end-points, enzyme induction requires the toxicant to initiate all of the biochemical steps from receptor binding through to DRE binding and mRNA transcription. Clemons et al.[134] have shown a good correlation in wild fish between TEQs determined by GC/MS and those obtained by EROD assay using either H4IIE cells or a rainbow trout cell line designated RTL-W1. This represents an important validation of the enzyme induction assay with real samples (see Figure 9a and b).

Considerable effort has recently been invested in comparing different monooxygenase enzyme assays because

![Figure 9 EROD induction by four nonortho coplanar PCBs (PCB 77, PCB 81, PCB 126, and PCB 169) and three mono-ortho coplanar PCBs (PCB 105, PCB 118, and PCB 156) in (a) H4IIE and (b) RTL-W1 (n ≥ 3). Sci., 53, 1177–1185 (1996).)](https://example.com/fig9.png)
Sanderson et al.\textsuperscript{138} compared the DL obtained from EROD analysis using H4IIE cells with the value obtained based on light emission from H4IIE cells that had been genetically modified to contain the luciferase reporter gene. The latter technique gave a threefold lower DL on exposure to TCDD (0.8 pmol L\textsuperscript{-1}). Hodson et al.\textsuperscript{137} compared the work of several groups with regard to DLs and ranges of quantitation in monoxygenase assays. Most of the studies reviewed report the induced EROD activity vs \(\log[\text{TCDD}]\), and so “ranges of linear response” actually refer to the almost linear central portion of the sigmoidal dose–response curves [see Figure 7a]. This accounts for the similarity between the reported EC\textsubscript{50} values and the DLs of the assay. For the commonly used rat hepatoma H4IIE cell line, typical results are a log-linear range about 10–200 pM TCDD, with an EC\textsubscript{50} of \(\sim 20\) pM TCDD and a DL of \(\sim 10\) pM TCDD.\textsuperscript{138} Primary chicken embryo hepatocytes show a log-linear range of about 1–100 pM TCDD, EC\textsubscript{50} \(\approx 20\) pM TCDD, and DLs of \(\sim 1\) pM TCDD.\textsuperscript{124} In the rainbow trout liver cell line RTL-W1, a log-linear range of about 2–20 pM TCDD, EC\textsubscript{50} \(\approx 15\) pM TCDD, and DLs of 2 pM TCDD were reported.\textsuperscript{134} Luciferase expression in reporter-gene assays in HepaG2 and Hepa1c1c7 cells typically demonstrated a wider log-linear range of about 10–1000 pM, but the EC\textsubscript{50} values and DLs were increased to approximately 100 pM TCDD and 50 pM TCDD, respectively.

Parenthetically, Hodson et al.\textsuperscript{137} also reviewed the use of passive devices based on semipermeable membranes for preconcentrating natural and effluent water samples in order to increase the concentration of DLCs prior to EROD analysis. By the choice of triolein inside the membrane, the deployment device is able to mimic, to some extent, the behavior of an aquatic organism in bioconcentrating these xenobiotics from water.

A limitation to the use of monooxygenase enzyme assays is that their activity may be species-dependent. Dubois et al.\textsuperscript{126} observed different patterns of dose vs EROD activity in quail hepatocytes, rat hepatocytes, and the human hepatoma line HepG2 when comparing enzyme induction by PCB 77 and the commercial PCB mixture Aroclor 1254. In experiments with rats, DeVito et al.\textsuperscript{110} found that the relative EROD induction potencies of different DLCs varied with the tissue tested, and they cautioned against the universal applicability of hepatic EROD induction potencies.

The curves of fluorescence intensity vs concentration for different inducers are displaced along the abscissa (Figure 9a and b), as would be expected for compounds with different TEFs, and so the abscissa of the curve for a mixture represents TEQ. EROD activity is a saturable response, because beyond a certain concentration of DLC all AhR sites have been occupied and CYP 1A1 production has been maximized. There are, however, two consistent findings that complicate the interpretation of data obtained from EROD assays: (1) different DLCs yield dissimilar values of the maximum (saturable) fluorescence intensity; and (2) for many DLCs, EROD activity declines when the concentration of the inducer exceeds the saturating value (Figure 10). This phenomenon has been the subject of some controversy.\textsuperscript{139} Recently it has been shown that DLCs not only induce CYP 1A1, but also act as competitive inhibitors of the deethylation of the enzyme substrate, 7-ethoxyresorufin.\textsuperscript{61,140} This leads to biphasic curves when cells in culture are treated with increasing amounts of the DLC: the EROD activity increases at low [DLC], as more enzyme is induced, but falls again once the induction response (which is AhR

\begin{figure}
\centering

\caption{EROD activity in primary rat hepatocytes incubated for 24 h with TCDD, 3-MC, PCB 77, or PCB 153. Activities are relative to the activity obtained following treatment with 1 nM TCDD. Error bars represent the standard deviation of the calculated EROD activities.\textsuperscript{89} (Redrawn from J. Petrulis, PhD Thesis, University of Guelph, 1998.)}
\end{figure}
mediated) has become saturated, because additional DLC inhibits the enzyme. The quantitative EROD response becomes further complicated when mixtures of inducing agents are present or when the inducer is metabolized concurrently with enzyme induction. This has also been implied by experiments in which the length of exposure of cells to the inducing agents is varied: the apparent EC50s of some DLCs increased at longer exposure times, on account of differential rates of metabolism. Furthermore, Aarts et al. disclosed that the extent of antagonism between TCDD and either PCB 77 or 2,2',3,3',4,4'-hexachlorobiphenyl (PCB 128) was species and cell-line dependent in luciferase reporter gene assays. For all these reasons, caution must be employed when using EROD and related enzyme assays in the mode of inducing enzyme activity by incubating cells with an environmental extract.

Competitive inhibition does not apply to the use of monooxygenase assays for assaying the enzyme activity of hepatic microsomes, when detecting prior exposure of wild-life to DLCs. In that application, there is no carryover of the DLCs into the microsomal preparation, and so competitive inhibition of the enzyme does not occur.

Another potential problem is the antagonism, or masking, of the effects of one DLC by another. This has been observed in the EROD assay by Hasspieler et al., who tested coplanar PCBs together with TCDD as inducers of EROD activity in the human hepatoma cell line HepG2. PCB 77 and PCB 169 had similar behavior: neither induced EROD activity alone, but each inhibited EROD induction by TCDD. PCB 126 was a weak EROD inducer on its own; it weakly antagonized induction by a high dose of TCDD, but had little effect at lower doses of TCDD. Similarly, Janz and Metcalfe found less than additive induction of AHH in intact rainbow trout treated with TCDD and PCB 77. In a 13-week, low-dose feeding study in rats, Van Birgelen et al. (1994) found evidence for nonadditive behavior between TCDD and PCB 156 in several end-points. These observations are consistent with target molecule antagonism, when high concentrations of DLCs compete for a limited stock of AhR, or with competitive enzyme inhibition. The combination of target molecule antagonism and competitive enzyme inhibition makes it clear that enzyme activity assays for CYP 1A1 may underestimate the TEQ of a complex environmental mixture.

Both the foregoing effects come into play in the interpretation of the study by Bosveld et al., who studied the effects of the interaction between TCDD and the nonplanar PCB 153 on EROD activity in chicken embryo hepatocytes. The ratio [TCDD] : [PCB] was kept constant at 1 : 104 for every dose of the toxicants, reflecting their typical ratio in environmental samples. EROD activity was found to peak at [TCDD] ≈ 1 nM, followed by a fall in activity as the TCDD concentration was increased further. Viability assays on the hepatocytes demonstrated that the decrease in activity was not due to cytotoxicity at the high doses of TCDD.

### 2.3 Markers of Abnormal Metabolism

A well-studied end-point following DLC exposure is the hyperaccumulation of hepatic uroporphyrin III (UP-III). As in all cases of abnormal metabolism, the question arises as to whether the end-point observed can be more than a marker of exposure, i.e. does it really parallel toxicity?

The overproduction of UP-III in the liver, and the related human disease porphyria cutanea tarda, are observed in animals following exposure to many halogenated aromatic compounds. The link to an AhR-mediated pathway was established by showing that inhibitors of cytochrome P450 1A1 suppressed the overproduction of UP-III [reviewed by Bonkovsky et al. (1995) and that UP-III accumulation paralleled AHH activity in AhR-responsive and -nonresponsive mice.

Later work revealed that the link between porphyrin metabolism and the induction of cytochrome P450 enzymes is an indirect one. UP-III is principally formed from uroporphyrinogen III by the action of cytochrome P450 1A2; when cytochrome P450 1A2 is induced [e.g. by nonplanar PCBs such as PCB 153], uroporphyrinogen III is diverted from its normal route in heme biosynthesis. Knockout mice lacking CYP 1A2 activity had less uroporphyrinogen oxidation activity than wild-type mice; in human hepatoma cells, CYP 1A1 and CYP 3A4 also contributed to uroporphyrinogen oxidation activity. Normally, heme suppresses the formation of uroporphyrinogen III through feedback inhibition, thus the

---

**Figure 11** The pathway of porphyrin metabolism, showing the proposed mechanism of hepatic porphyrin accumulation. (Redrawn from A.P.J.M. van Birgelen, J. Van der Kolk, K.M. Fase, I. Bol, H. Poiger, M. Van den Berg, A. Brouwer, Toxicol. Appl. Pharmacol., 126, 202–213 (1994).)
diversion of uroporphyrinogen III causes a build-up of UP-III (Figure 11).

Studies on rats dosed with mixtures of TCDD and PCB 153 showed that the effect of the two compounds was highly synergistic. Neither TCDD alone nor PCB 153 alone promoted significant accumulation of UP-III, which most likely involves the induction of both CYP 1A1 and 1A2. In addition to monoxygenase induction, TCDD induces δ-aminolevulinic acid synthetase, which is required for the further synthesis of uroporphyrinogen III. The 1A2 isozyme is induced by the nonplanar PCB, thereby promoting the oxidation of uroporphyrinogen III to UP-III. Although porphyrin accumulation can be regarded as an AhR-mediated process, the interactive effects among DLCs are clearly complex, and not completely understood.

The accumulation of hepatic porphyrin in chicken embryos has been suggested as a useful marker for the exposure of avian species to DLCs. Individual DLC congeners had broadly similar relative potencies with respect to EROD induction and porphyrin accumulation in primary hepatocytes from chicken and pheasant. Interactive effects between TCDD and several PCB congeners have been studied in primary chicken hepatocytes. For both planar and nonplanar PCBs it appeared that significant porphyrin accumulation only occurred at doses higher than those at which EROD induction was maximum (where the occupancy of the AhR is also maximum). One of the combinations examined by Tyshkild et al. was TCDD + PCB 153. At a fixed concentration of TCDD that caused maximum EROD induction but no porphyrin accumulation, increasing levels of the PCB depressed EROD activity and led to porphyrin build-up. We can explain the depression of EROD activity (primarily CYP 1A1) in terms of target molecule antagonism (PCB outcompeting TCDD from AhR binding sites) and competitive enzyme inhibition; this must occur at a PCB concentration that does not induce maximum CYP 1A2. These interactive effects among DLCs make it difficult to calibrate porphyrin accumulation as a quantitative assay for evaluating the toxic potency of environmental samples. Complicating the matter further is the observation that the extent of porphyrin production in the liver following exposure to PCBs is apparently related to the concentration of iron in the liver, an additional parameter that would need to be addressed in the development of a quantitative assay.

3 IMMUNOASSAYS

Immunoassays depend upon the recognition of an antigen (or foreign molecule) by an Ab, which is a soluble protein that has been produced by B-lymphocytes in a live animal. Exposure to a particular antigen causes the proliferation of the B-cell clone that produces the antigen-specific Ab, such that an immune response can be mounted in response to a subsequent exposure to the antigen. Immunoassays are based on exploiting the high affinity of an Ab for the antigen to which it was raised. The actual assay requires both the recognition and quantitation of free analyte in a test solution; the latter is usually accomplished using a competition assay, although a wide variety of assay methods has been described [reviewed by Sherry].

Immunoassays can be used to detect and quantify large biomolecules such as specific proteins or parts of proteins, polysaccharides, or nucleic acids at low concentrations, e.g. <10 fmol of the N-terminal region of the AhR itself. They have become standard methods of analysis in clinical laboratories, where they have been adapted for use in the rapid, automated analysis of large numbers of samples.

Antibodies are normally produced in response to molecules having molecular mass >1000. Small molecules such as TCDD therefore do not elicit an immune response on their own, and so the antibodies must be raised by covalently binding the small molecule (termed a hapten) to a carrier protein that can produce a response and then injecting the conjugate into a live animal. For TCDD analysis, an extensively used hapten is 1-(N-adipylamino)-3,7,8-trichlorodibenzo-p-dioxin, which is a TCD molecule one of whose chlorine substituents is replaced by a linking moiety that connects it covalently to the carrier protein (Figure 12). If such a protein–hapten conjugate is injected into a live animal, some of the antibodies produced may subsequently be able to recognize the hapten–protein conjugate while others may recognize only the unattached hapten.

Antibodies produced as just described are termed polyclonal antibodies: they are produced by multiple clones of cells, each of which contributes one type of Ab. The antibodies bind to the antigen by way of many different specific recognition elements or epitopes that are functions of the size, shape, and hydrophobicity of different regions of the protein–hapten conjugate. Most of the polyclonal antibodies will interact with epitopes on the carrier protein itself, rather than recognizing the hapten. Even if the hapten is part of the recognition site.

Figure 12 Structure of the protein conjugate of 1-(N-adipylamino)-3,7,8-trichlorodibenzo-p-dioxin.
it is unlikely that an Ab will recognize the hapten alone, rather than the hapten plus part of the carrier, unless the hapten has a molecular mass above 1000.

Polyclonal Ab assays for DLCS were reported around 1980 [for TCDD, Albro et al.; for TCDF, Luster et al.]. In these assays the DLC molecule was bound covalently to the carrier protein by an N-adipylamido chain, and the antibodies were produced in rabbit. The assay was carried out by a radioimmunological method in which the unlabeled DLC and the appropriate N-adipylaminotrichlorobenzo furan or -dibenzo-p-dioxin, labeled with $^{125}$I in the adipyl chain, competed for the Ab. The complexed antibodies were precipitated with goat anti-rabbit y-globulin and $y$-counted for $^{125}$I. The greater the concentration of unlabeled DLC, or in the case of cross-reactivity experiments the higher its affinity for the Ab, the less radioactivity was detected in the pellet. For pure TCDD, as little as 0.08 pmol could be detected by this method. Competitive radioimmunoassays suffer from the same disadvantages as competitive ligand binding assays: it is the labeled competitor rather than the analyte that is actually detected, and the response is saturable, with the signal (bound radioactivity) declining to zero as the concentration of the analyte increases.

A general problem with polyclonal antibodies is poor recognition of the hapten and interference by those antibodies that recognize different structural motifs. In addition, the particular range of antibodies formed varies with time in a given preparation, and from animal to animal among different preparations, making it impossible to standardize methods between different laboratories. These limitations can be avoided by the use of a monoclonal Ab, which is a unique protein derived from a single cloned cell line, and which can recognize the analyte specifically. Rather than attempt to separate a single protein from the polyclonal Ab mixture, a more successful approach is to separate the individual cells that produce the specific monoclonal Ab. This is done by fusing cells from an immortal cell line to spleen cells that have been previously exposed to the protein-linked hapten. The resulting hybridomas are then screened to select a particular cell that secretes an Ab that recognizes the hapten. With luck, a hybridoma can be selected with the ability to form antibodies that recognize specifically the free ligand; this cell line can then be grown up indefinitely in culture.

The monoclonal Ab is uniform and can be distributed to different laboratories, allowing the development of standardized assay procedures. Among the advantages of an optimally selected monoclonal Ab are ease of use, minimal sample preparation, low cost per sample, reproducibility, high selectivity for the analyte, small sample size, and potential for both automation and use in the field. Disadvantages include the long development time and high cost of obtaining the monoclonal Ab, including hapten synthesis and screening thousands of hybridomas, and problems of cross-reactivity from related and unrelated analytes. The latter problem means that independent (chemical) confirmation of the analyte responsible for the response is necessary. In addition, a single immunoassay cannot respond to analytes of different structural types as can a chemical assay such as GC/MS.

In the case of TCDD analysis, monoclonal antibodies were first developed by Kennel et al. and Stanker et al., in an attempt to improve specificity. In recent work, this group reported haptenas based on 2-alkenyl-3,7,8-trichlorodibenzo-p-dioxin used by Stanker et al., in an attempt to improve specificity. In recent work, this group reported haptenas based on 2-alkenyl-3,7,8-trichlorodibenzo-p-dioxin used by Stanker et al., in an attempt to improve specificity. In recent work, this group reported haptenas based on 2-alkenyl-3,7,8-trichlorodibenzo-p-dioxin used by Stanker et al., in an attempt to improve specificity.
An alternative protocol involves immobilizing the Ab on plastic in 96-well plates. This is incubated with the test DLC mixture and a fixed aliquot of a competitor–enzyme conjugate. After removing the solution phase, the enzyme substrate is added and the amount of enzyme product is determined by how much competitor–enzyme conjugate is bound to the Ab (again, the less DLC in the sample, the more enzyme product is formed). DLs in the range of 0.1 ng of TCDD have been reported,\textsuperscript{165} using a mouse monoclonal Ab having specificity for tetra- and pentachlorinated dibenzo-p-dioxins that roughly parallels their I-TEFs. A similar approach was used to prepare monoclonal antibodies that recognized coplanar PCBs in the presence of larger amounts of the nonplanar congeners,\textsuperscript{166,167} using as the hapten a 4-alkoxy-3,3′,4′-trichlorobiphenyl linked to the protein through a terminal carboxyl on the 4-alkoxy substituent. However, various “PCB fragments” (i.e. substituted dichlorobenzenes) were more reactive with the Ab than PCB 77 which severely limited the usefulness of this approach. A recently reported electrochemical immunosensor is claimed to overcome this problem;\textsuperscript{168} the Ab is immobilized on an electrode surface by entrapment in an electrically conducting polypyrrole matrix. The signal in this case was the current produced in response to a pulsed voltage waveform on the sensing electrode. Linear calibration curves for Aroclor mixtures were obtained up to (at least) 100 ng L\textsuperscript{−1}, and DLs of 0.4–3 ng L\textsuperscript{−1}, depending on the Aroclor mixture, with low cross-reactivity with non-PCB chlorinated compounds.

In principle, monoclonal antibodies could be developed as probes to recognize individual DLCs, by screening appropriate hybridomas. In practice, this has not been very successful because of problems of cross-reactivity.\textsuperscript{158} The recognition sites on monoclonal antibodies are fairly large (\sim 2−3 nM in diameter) compared with the size of the analyte of interest (0.3 \times 1.0 nM in the case of TCDD), and so other molecules of similar size and hydrophobicity can be accommodated almost equally well.\textsuperscript{169} This makes the monoclonal Ab assay more applicable to DLCs as a class than to the quantitation of individual DLC congeners. A calibration curve can be constructed using test solutions containing known concentrations of TCDD, in which case the assay measures the total concentration of DLCs as TCDD equivalents.

An ongoing criticism of Ab methods for assaying DLCs is that their higher DLs compared with GC/MS. The group at Cape Technologies has successfully validated their enzyme immunoassay down to the picograms per gram level for both fly ash\textsuperscript{170} and soil\textsuperscript{171} samples, with excellent linearity between enzyme immunoassay and GC/MS methodologies. Sugawara et al.\textsuperscript{172} have recently introduced a polyclonal ELISA for TCDD with a DL of \textless 1 pg per well, based on horseradish peroxidase activity as the enzymatic detection system. Hapten–protein conjugates were based on 2,3-dichloro-7-(3′-propenoic acid) derivatives. A point of interest was the use of 2-methyl-3,7,8-trichlorodibenzo-p-dioxin as a less toxic surrogate for TCDD; the two compounds behaved almost identically in the assay.

To a limited extent, an assay for DLCs based on monoclonal antibodies resembles the competitive AhR ligand binding assay (section 2.1.2). In each case a protein is used to complex the DLC, and a reference ligand (in this case the immobilized hapten) and the DLCs in the test solution compete for a limited amount of protein. Because the monoclonal Ab recognizes the ligand, its binding site is a model for the binding site of the AhR: how accurate a model depends on the similarities between the binding sites, which is a matter of chance. Cross-reactivity between DLCs is observed because each DLC in the sample binds to the Ab according to its relative affinity and its concentration. Therefore, the TEQs obtained by immunoassay may differ from those from the receptor binding assay, because of different relative affinities of DLCs for the two proteins. The immunoassay is not mechanism based because the DLCs do not interact with the Ab as part of the biological mechanism of action.

Like the AhR binding assay, immunoassays tend to be conservative in recognizing more analytes than are toxicologically relevant. This has already been noted in the case of recognition of “PCB fragments” \textsuperscript{166} and was also observed by Stanker et al.\textsuperscript{158} and Vanderlaan et al.\textsuperscript{169} who compared immunoassays of several environmental matrices to analyses by GC/MS. Immunoassays consistently showed more of the “toxic” PCDDs and PCDFs than GC/MS, and in some cases the discrepancy was substantial.

Another aspect of DLC toxicology that has been exploited as a bioassay is immunosuppression. Spleen cells from a test species are combined with sheep red blood cells (SRBCs) and DLCs. After 5 days, the spleen cells are resuspended and plaqued. The number of plaques in the red blood cell lawn are counted and reported relative to the number of viable cells. DLCs have been demonstrated to cause a concentration-dependent suppression of the splenic plaque-forming cell (SPFC) response to SRBCs.\textsuperscript{173} The utility of this technique as a screening assay is questionable as recent studies have shown that the response to mixtures of DLCs is not additive. The assay is very sensitive to TCDD, causing significant suppression at doses as low as 1 μg kg\textsuperscript{−1}, but PCB 153 has actually been found to enhance the response.\textsuperscript{174}
4 EARLY LIFE STAGE BIOASSAYS

Interest in this research area has recently been high because of the recognition that the AhR may be necessary for proper development in a wide range of tissues. In addition, AhR binding substances may alter the actions of endogenous hormones indirectly; for example, exposure to TCDD increases the rate of metabolism of estradiol, presumably by upregulating CYP 1A enzymes. In utero exposure to DLCs causes clear reproductive abnormalities in rodents, and there is limited evidence for such effects also in humans. Willey et al. have shown that the AhR is transcriptionally activated during development in tissues known to be adversely affected by exposure to DLCs. To date, no endogenous ligand for activating AhR during development has been identified.

TCDD shows dose-dependent AhR-mediated teratogenicity in mice, with the most prominent effect being cleft palate. The dams are exposed to TCDD around days 7–10 of gestation and killed on day 18 for examination of the fetuses. Besides being inconveniently time consuming and requiring large numbers of animals, this end-point shows marked interactive effects between PCBs and TCDD. Certain nonplanar PCB congeners are able to antagonize TCDD-induced teratogenicity when administered at doses in the range of 10^4 times the teratogenic dose of TCDD, while planar PCB congeners are themselves teratogenic. The rationalization of these observations is that PCBs and TCDD compete for a finite quantity of AhR. The complexes formed between the AhR and TCDD, and between the AhR and the toxic PCBs go on to cause the teratogenic response, whereas the complexes formed with the protective PCBs do not. When the total receptor occupancy is high, a nontoxic or antagonistic substance can protect against the effects of a toxic substance by binding unproductively to the AhR, thus in a sense displacing the toxic ligand. This effect is not seen at low total receptor occupancy when there are sufficient receptor molecules available to bind all ligands.

Recent interest in environmental estrogens, and the more general phenomenon of endocrine disruption, have focused attention on the role of TCDD (and potentially other DLCs) in developmental and reproductive toxicology. Although the mechanisms of action are not yet clear, it is already apparent that TCDD has strong interactive effects with steroid hormones (although there is no cross-reactivity between TCDD and steroid hormone receptors). In one recent paper, TCDD was shown to block the binding of the estradiol–estrogen receptor complex to estrogen response elements on DNA, while conversely estradiol blocked the association of the TCDD–AhR complex to DREs. TCDD and other DLCs, notably 6-methyl-3,7,8-trichlorodibenzo-p-dioxin, inhibit the growth of the MCF-7 human breast cancer line. TCDD is also developmentally toxic to laboratory rats, causing demasculinization of male pups when administered at sublethal doses to the dams during gestation. These effects, which persist into maturity, may be due to TCDD-induced elevation of the levels of mixed-function oxidase (MFO), thereby enhancing the metabolism of steroid hormones, but this has not yet been demonstrated experimentally. These recent observations have led to interest in developing assays to test for adverse effects of DLCs in early stages of life.

The interest in developmental toxicity is not really new, because some of the earliest concerns of TCDD exposure were “toxic fat syndrome” in young chickens in the 1960s, and the debate in the 1970s over whether forest spraying programs could cause human birth defects and miscarriages. Both of these situations involved the use of the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), which contained parts per million levels of TCDD as a contaminant introduced during manufacture.

In the case of toxic fat syndrome, a characteristic finding was the development of pericardial edema in newborn chicks, whose early death caused substantial economic loss in the broiler chicken industry. Higginbotham et al. suggested this as a bioassay end-point. In related work, Flick et al. showed a dose-dependent reduction in hatchability when eggs were treated with TCDD. Rifkind et al. correlated histopathological changes including hepatic edema in chick embryos with the induction of AHH and EROD activity, and Brunnström correlated hatchability with EROD induction, in each case after dosing eggs with various PCB congeners. Helder demonstrated the toxicity of TCDD towards fish and their embryos, and developed an assay based on the lethality of DLCs towards yolk sac fry of Salmo gairdneri. Similar assays have been introduced for rainbow trout, fathead minnow, and Japanese medaka. In more recent studies, the toxicants have been injected into the developing fish, rather than exposure through the water, to control the dose more precisely. Other techniques, see Metcalfe et al. Walker et al. found that pairs of PCDD and PCB congeners behaved nearly additively (no deviations greater than 2–3-fold) in an early life stage assay in rainbow trout. The same group assessed a complex PCDD–PCDF–PCB mixture in lake trout as having close to the additive lethality of its components. LD_50s were in the range of 200 pg of TEQ per egg. A disadvantage of these protocols is the relatively long assay time (several weeks).

The Japanese medaka (Oryzias latipes) is a small fish that is convenient for laboratory assays because it is easily reared in captivity, it can be induced to lay eggs in the laboratory all year round, and its larval envelope is transparent, permitting easy evaluation of developmental toxicity in addition to mortality. Wisk and Cooper
studied the survival of Japanese medaka embryos to 3 days post-hatch, after exposing the embryos to test chemicals within 1–2 h after fertilization. The LC₅₀ for TCDD was 13 ng L⁻¹ (40 pM) nominal concentration and, as in mammalian systems, the congeners that were fully chlorinated in the 2-, 3-, 7-, and 8-positions were substantially more toxic. An AhR-mediated mechanism of toxicity is apparent in that neither lethality nor morphological change is seen until after the formation of the liver, and lethality occurs in the same concentration range as AHH induction. In addition to synthetic DLC mixtures, Harris et al. have demonstrated that lipophilic extracts from rainbow trout taken from Lake Ontario are embryotoxic to the Japanese medaka.

The effect of DLCs on the immune systems of intact animals has been known for many years; a dose-dependent reduction in thymic weight in rodents is observed. This was shown to be an AhR-mediated response by correlating the immunotoxic activities of different DLCs with their ability to induce monooxygenase enzymes. Numerous interactive effects on these end-points involving TCDD and PCB congeners have been reported yielding evidence that certain PCB congeners can mask the activity of TCDD. Smialowicz et al. treated mice with TCDD and PCB 153, alone or in combination, and examined both thymus weights and the ability of their spleen cells to form plaques upon treatment with SRBCs. PCB 153 alone had little effect on either end-point, but depending on its dose it could either enhance or suppress the responses of TCDD. Such complex interactive effects make it unlikely that a broadly useful bioassay for DLCs could be developed, using these end-points.

5 CELL PROLIFERATION ASSAYS

Knutson and Poland developed an assay system for TCDD based on culturing the XB keratinocyte cell line, which is derived from a mouse teratoma. When cultured at low cell density in the presence of lethally irradiated 3T3 fibroblasts as feeder cells, the XB cells replicate and differentiate to give characteristic flattened, keratinized cells that are identifiable both by their shape and because they stain red with the dye Rhodanile Blue. At high cell density, the XB cells replicate but do not keratinize. However, low concentrations of TCDD cause the high-density cultures to keratinize in a dose-dependent fashion; therefore, the extent of keratinization can be correlated with the intensity of color development when the cells are stained. Keratinization requires a minimum concentration of TCDD of 50 pM; additionally, the efficacy of keratinization by a PCDD congener roughly parallels its binding affinity for the AhR, and thus suggests that this is a mechanism-based assay. This assay was shown to be applicable to other DLCs such as TCAB. A drawback to the assay is the relatively long incubation time that is required (nearly 2 weeks), which mitigates against the use of the assay for following the progress of a remediation “on the fly”.

A variant of the keratinization assay, introduced by Gierthy and Crane, employed a strain of XB cells denoted XBF. These do not keratinize in the presence of TCDD, but during a 14-day incubation form “cobblestone-like” cells (flat cells) that can be visualized by staining. The DL in this assay is 10 pM TCDD in the culture medium, with PAHs having 10⁻³–10⁻⁴-fold less response than TCDD. The flat-cell assay correlated linearly with chemical analysis by GC/MS for a series of soot samples that were contaminated with PCDFs. It showed semiquantitative agreement with chemical analysis for the DLC content of a range of fish tissue and sediment samples and of several transformer fluids. As a related end-point, one of the most characteristic and well-documented responses of halogenated aromatic compounds in humans is chloracne, caused by hyperkeratosis of squamous skin cells. This end-point can also be seen in experimental animals such as rabbits and hairless mice. Indeed, an early example of a bioassay for DLCs was the production of chloracne in the rabbit pinna.

One of the characteristic responses of DLCs is an increase in cell proliferation, which is linked mechanistically to a change in the binding between the epidermal growth factor and its receptor. Cancers induced by TCDD also appear to be principally those of epithelial cells.

6 CONCLUSIONS

Present regulations establish allowable concentrations of DLCs either on the concentration of TCDD or the total TEQ of named congeners, based in each case on congener-specific analysis. Under these circumstances bioassays can never replace an “absolute” analytical method such as GC/MS because they do not provide chemical identification. However, an inexpensive and rapid bioassay can usefully act as a screening tool based on a “cut-off” TEQ, to eliminate negative samples from further analysis. This could greatly reduce costs, especially if most samples are expected to have low levels of contamination and the assay has a low rate of false positives.

We have noted that AhR binding assays and immunoassays tend to have high false-positive rates (a “conservative” feature) because they respond to substances that bind to the receptor (or Ab) without causing toxicity. A
critical limitation occurs when screening assays have a significant rate of false negatives, which imply incorrectly that a contaminated sample is “clean”. Enzyme induction and porphyrin accumulation are examples of assays in which one DLC may mask (antagonize) the dioxin-like activity of another, and an analyst cannot be confident that the TEQ obtained from the assay is a true reflection of the TEQ of the sample. Such assays are of limited value in screening programs unless interacting analytes are independently known to be absent; however, they may remain viable options for monitoring the progress of a remediation project.

The question of biological relevance always arises with an assay based on a biological principle. Whereas human health concerns might be addressed by an enzyme induction assay, preferably using a human cell culture, protection of fish in an aquatic environment might suggest an early life stage assay to monitor the potential for reproductive or developmental abnormalities. It is unrealistic to imagine that a single procedure will be applicable to all situations.

Dyes, Environmental Analysis of

J. Riu and D. Barceló
IIQAB–CSIC, Barcelona, Spain

1 Introduction

Large quantities of dyes are produced for diverse applications, including textiles, paper, paint pigments, printing inks, and food coloring. According to recent information, nearly 20% of the world dye production, which rose more than 10% annually to 2.2 billion lb in 1994, is manufactured in Western Europe.(1) The textile industry is the largest consumer of these products, accounting for two-thirds of the dyestuff market. Since intermediates and degradation products of synthetic dyes can be potential hazards owing to their toxicity or carcinogenicity, they are of major environmental interest. The analysis of dyes poses special problems because these products do not belong to a single group of chemical compounds, but encompass many chemical functionalities with large differences in solubility, volatility, ionization efficiency, and other properties. Additional complications in the analysis of sulfonated azo dyes exist because some of the manufacturing precursors to dyes are carried over to, and are not removed from, the final product. The result is a complex mixture containing the dye itself and several other interfering compounds.

In the nomenclature of dyes it is important to differentiate between dye classification and dye use. Dye classification is based on the major chromophore functionality of the dye, the main classes being azo (including the sulfonated azo dyes), anthraquinone, polymethine, phthalocyanine, sulfur, arylmethane, stilbene, and coumarin dyes. The use of a dye generally refers to the manner in which it is applied. Some of the most common applications are in acidic or basic media, as mordants, lakes, pigments, solvents, or dispersants. Figure 1 shows some typical structures of the main groups of dyes.

Dyes which are widely used in the textile industry to color natural fibers, may possess acid groups in their chemical structure. Especially, sulfonic acid groups are often present as sulfonate anions and provide very good water solubility. Recent estimates indicate that approximately 12% of the synthetic textile dyes used each year are lost to waste streams during manufacturing and processing operations and that 20% of those losses will enter the environment through effluents from wastewater treatment plants.(2) These compounds are difficult to remove in water-treatment procedures and, because of their high water solubility, they can be transported from municipal sewers through to rivers. In addition, dyes have been shown to undergo reduction in natural waterways and the environment and the degradation products include amines, which are known to be carcinogenic. Their presence in effluents and industrial wastewaters is of considerable interest because of their potential to contaminate groundwater and drinking water supplies.(3) Therefore, the detection, identification, and quantification of dyes at low levels in the aquatic environment is important for the protection of natural waters.

Most dyes are nonvolatile and thermally unstable, and consequently cannot be analyzed by gas chromatography (GC). For this reason, LC/MS was applied to the analysis and confirmation of the dyes. Current official analytical...
methods for disperse azo dyes, e.g. United States Environmental Protection Agency (USEPA) 8321A, are based on preconcentration methods followed by TSP/LC/MS, but are not applicable for sulfonated azo dyes (see Table 1). Problems were encountered with this interface for this kind of compound.

With the development of API LC/MS interfaces, good sensitivity and structural information can be achieved as compared with other LC/MS interfacing devices such as TSP or particle beam (PB).

CE is a powerful alternative to classical chromatographic techniques for the separation of polar and ionic analytes because of its high separation efficiency and low solvent costs. It can be useful for overcoming the problems of LC in the separation of sulfonated azo dyes. In this respect, a major objective of the analytical chemistry

![Figure 1](structures.png)

**Figure 1** Structures of some examples of the most important groups of dyes.
program at USEPA’s National Exposure Research Laboratory (Las Vegas) is to foster and advance the adoption of new environmental monitoring technologies, especially those suited to pollutants for which conventional analytical approaches fail. An analytical separation technique that has enormous potential for environmental analysis is CE. One of the broad areas of great potential for CE in environmental monitoring is outlined in the goals adopted by USEPA and set forth in its Environmental Technology Initiative (ETI) formulated in 1993. Under ETI, environmental monitoring technologies are sought that offer continuous monitoring capabilities, are inexpensive, are exportable to foreign countries, are low generators of waste, minimize exposure of personnel to hazardous chemicals, and address a broad range of analytes. These widely divergent goals could be easily addressed by CE in its various formats.

An overview of the current analytical methods for the determination of dyes in environmental matrices is presented, and aspects such as sample extraction and preconcentration strategies are also discussed.

2 LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

Most azo dyes are nonvolatile and thermally unstable compounds and consequently they cannot be analyzed directly by GC. Therefore, USEPA has validated a method for several azo dyes and anthraquinone dyes, not including sulfonated azo dyes. The method is based on LC with ultraviolet (UV) and/or TSP/MS detection. Prior to analysis by high-performance liquid chromatography (HPLC) the target analytes are extracted by liquid–liquid extraction with methylene chloride for water samples or methylene chloride–acetone (1:1) for solid samples.

Some problems exist in the determination of sulfonated azo dyes by LC/TSP/MS and are discussed below.
Other LC/MS interfaces for the determination of sulfonated dyes have been tested such as the PB. Straub et al. \(^\text{17}\) studied the mass spectra of some azo dyes including four solvent dyes, nine disperse dyes (one of which was a diazo dye), and one acid dye (the disulfonated azo dye Acid Orange 10).

With an HPLC/MS system using a PB interface it is possible to record the electron ionization (EI) mass spectra and gain useful structural information on these dyes. In addition, in some instances, additional organic impurities derived from decomposition, the coupling reaction process, or from external sources during the handling of commercial products, could be identified by HPLC/PB/MS. Characteristic fragmentation in azo dyes included cleavage of the C–N bonds on either side of the azo linkage, and cleavage of the N=N double bond with transfer of one or two hydrogen atoms, to form an imine or amine, respectively. Most azo dyes showed a molecular ion, and fragmentation from ring cleavage was observed. Naphthol-containing azo dyes presented [M – CO\(^+\)] and [M – HCO\(^+\)] fragment ions, which are not very intense but characteristic of a hydroxyl group on an aromatic ring. The acid sulfonated azo dye showed a spectrum which indicated that complete desulfonation (m/z 246) was thermally accomplished in the mass spectrometer, in addition to characteristic fragment ions of naphthol-containing azo dyes. Detection limits of the compounds studied were in the range 500 ng–5 μg but the exact detection limit for Acid Orange 10 was not reported. LC/PB/MS was found to be two or three orders of magnitude less sensitive than TSP. The reduction products of Acid Orange 10 were identified by Voyksner et al. \(^\text{19}\) These products are formed in industrial sludge and can be more harmful than their precursors.

Several desorption ionization methods have also been used for the analysis of sulfonated azo dyes. Ventura et al. \(^\text{19}\) studied the spectra of some sulfonated dyes used in the industrial area of Barcelona (Spain) by fast atom bombardment (FAB) MS, including nitro, monoazo, diazo, trisazo, oxazine, and anthraquinone dyes. The behavior of the studied dyes varied widely. Cationized molecular ions, cleavage of azo groups, and loss of sulfonate from protonated or cationized molecular ions were the major common features. HPLC fractions of real water samples were analyzed with quantification limits that ranged from several nanograms to the low microgram level. However, because of low sample purity, modern dyes cannot be analyzed using the above-mentioned direct-probe techniques. This problem can be solved with the combination of a powerful separation technique, such as LC/MS.

### 2.1 Thermospray

TSP is a widely effective LC/MS technique because it can handle conventional LC solvents and chromatographic flow rates into the MS system and provides ionization for nonvolatile or thermally unstable samples. Therefore, TSP has been applied to the determination of dyes. Ballard and Betowski \(^\text{15}\) reported detection limits between 15 and 200 ng for several dyes belonging to six different classes with a TSP interface coupled to a triple-stage quadrupole. This technique worked well for some representative dyes of the azo, methine, arylmethane, anthraquinone, coumarin, and xanthene classes, but it was less effective for the sulfonated azo dyes.

The negative-ion TSP mode of operation was found to be less sensitive than the positive-ion mode by a factor of 10. Switching the filament on can be a way to improve the structural information of the TSP ionization, as shown by Voyksner \(^\text{110}\) with azo, diazo, and anthraquinone dyes in wastewater and soil. Detection limits of 10 ppt and 100 ppb in wastewater and soil, respectively, were achieved. The commercial diazo and anthraquinone dyes proved to be very complex mixtures of nearly 40 alkyl-substituted dye components, making monitoring and identification of a particular dyestuff difficult.

Flory et al. \(^\text{111}\) investigated various factors that could affect the TSP response for nine sulfonated azo dyes. They found that too high concentrations of ammonium acetate buffer suppresses the ionization of these anionic dyes since the more volatile acetate anion will eject instead of evaporation of the dye anion.

The sensitivity problem of the TSP interface in the analysis of sulfonated azo dyes has been investigated by several authors and different solutions were given. Yion et al. \(^\text{112,113}\) recommended the use of a wire repeller placed in the opposite side of the ion extraction funnel. An increase of about two orders of magnitude was obtained with the wire repeller and the spectra of several sulfonated azo dyes could be recorded. In some instances, losses of NaSO\(_3\) and 2NaSO\(_3\) were observed in many sulfonated dyes with the replacement of these groups by hydrogen atoms. Rafols and Barceló \(^\text{114}\) found that for Acid Red 14, which has two NaSO\(_3\) groups attached to different rings, both groups were lost. For Acid Blue 113, Acid Red 1, Mordant Red 9, and Acid Yellow 23, with two sulfonated groups in different rings, loss of only one group could be found. Owing to the above-mentioned controversy, it was suggested that, apart from the fact that the SO\(_3\) groups are attached to different rings, other reasons related to their chemical structure make it difficult to lose the second NaSO\(_3\) group. Losses of Na\(^+\) or 2Na\(^+\) are common in all sulfonated dyes with replacement of these groups by hydrogen atoms. As an example, the TSP spectra of Acid Red 73 are shown in Figure 2.

The repeller-activated collisionally induced dissociation (CID) mass spectra of some dyes \(^\text{115}\) was also compared with those obtained by TSP/MS with CID and
DYES, ENVIRONMENTAL ANALYSIS OF

In summary, we can conclude that TSP gives, in most cases, poor structural information (tandem mass spectrometry (MS/MS) can be a solution for this problem) apart from molecular weight and some losses, e.g. SO$_3^-$ from sulfonated azo dyes.

With reference to sensitivity, although most classes of dyes can be analyzed, good detection limits for monosulfonated and specially for polysulfonated azo dyes are difficult to achieve.

2.2 Atmospheric Pressure Ionization Interfaces

There are several interfaces which are classified as API interfaces, and that are given different names, but all of them have common features.$^{(16)}$

by EI. Common ions were found between these ionization modes.

McLean and Freas$^{(16)}$ modified a TSP/LC/MS system in order to improve the sensitivity for the analysis of some dyes by restricting the vaporizer exit orifice and adding a needle-tip repeller to the ion source. An increase in signal response was achieved for disulfonated azo dyes in the negative-ion mode. The TSP mass spectra contained mainly [M − Na]$^-$, [M − 2Na]$^{2-}$ and [M − 2Na + H]$^+$ ions.

Quantitative determination of disperse azo dyes has been carried out in a municipal wastewater treatment plant. The investigation of the fate of disperse azo dyes in the activated sludge process was the main objective of the study. Although the identification of two major reduction products of Disperse Red 1 by TSP/MS/MS could be achieved by Betowski et al.,$^{(17)}$ the mechanism of this reduction was unclear. Limits of detection of 180 pg for Disperse Red 1 in selected reaction monitoring could be achieved.

In Figure 2, the spectra of Acid Red 73 with TSP/MS positive ionization (PI) and negative ionization (NI) are shown.

![Figure 2](image-url)

Figure 2 Spectra of Acid Red 73 with TSP/MS positive ionization (PI) and negative ionization (NI).

In Figure 3, the flow injection/ESP mass spectra of 100 ng µL$^{-1}$ of Acid Orange 10 at collision activated dissociation (CAD) voltage of (a) −100, (b) −200 and (c) −300 V are shown.

![Figure 3](image-url)

Figure 3 Flow injection/ESP mass spectra of 100 ng µL$^{-1}$ of Acid Orange 10 at collision activated dissociation (CAD) voltage of (a) −100, (b) −200 and (c) −300 V.
API techniques of pneumatically assisted ionspray (ISP) and electrospray (ESP) have been used for the analysis of dyes.\textsuperscript{19,20} ESP achieves the best sensitivity for compounds that are already charged in solution.\textsuperscript{21} For this reason the initial work with ESP/MS focused on ionic dyes such as sulfonated azo dyes which were difficult to analyze by PB or TSP, as was shown in the work of Straub et al.\textsuperscript{7} While the disulfonated azo dye Acid Orange 10 showed a weak [MH – 2Na + 2H\textsuperscript{+}] ion in TSP ionization, and underwent considerable thermal degradation in EI with a PB interface, ESP in the negative-ion mode was able to detect characteristic anions formed in the solution. The negative-ion ESP spectra of this dye were recorded under three capillary–skimmer potential differences of −100, −220, and −300 V (see Figure 3). Lower potential differences resulted in the formation of singly charged ions [M – Na\textsuperscript{−}], [M + H – 2Na\textsuperscript{−}], and a doubly charged [M – 2Na\textsuperscript{2−}] ion. Higher potential differences resulted in more fragmentation with some losses in sensitivity. The base peak at m/z 151 [HOC\textsubscript{10}H\textsubscript{4}(SO\textsubscript{3})\textsubscript{2} + H\textsuperscript{+}] disappeared and [M – 2Na – SO\textsubscript{3} + H\textsuperscript{+}] and SO\textsubscript{3}\textsuperscript{−} ions at m/z 325 and 80, respectively, appeared from cleavage of a sulfonic group. The ESP/MS detection limit in negative-ion operation under full-scan MS conditions was 10 ng. In contrast, positive ESP ionization of Acid Orange 10 showed an almost 50-fold lower sensitivity. Only a weak [M + Na\textsuperscript{+}] ion was identified at positive potentials of 100, 240, and 300 V.

Rafols and Barceló\textsuperscript{14} studied the spectra of 11 sulfonated azo dyes by negative ISP ionization. They found an optimum extraction cone voltage of 20 V to obtain the maximum sensitivity and enough fragmentation to have structural information. The detection limits for the compounds studied varied between 1 and 80 ng. All the

SIM/PI, Selected ion monitoring/positive ionization.
DYES, ENVIRONMENTAL ANALYSIS OF

Dyes in this study were acid compounds and only the negative-ion mode of detection was used. Additionally, calibration graphs with acceptable correlation coefficients were obtained, demonstrating that quantification is feasible with LC/API/MS techniques. Calibration equations for ISP interfaces in the range 1–80 ng and 600–800 ng, depending on the compound, were calculated. The authors also studied the calibration graphs by using a heated pneumatic nebulizer interface (or atmospheric pressure chemical ionization (APCI) interface). This interface provides more structural information than ion evaporation, and can handle chromatographic flow rates up to 1–2 mL min\(^{-1}\). The technique was found to be less sensitive than the ISP interface with the exception of Mordant Red 9, a sulfonated dye that exhibits COONa and OH groups that give the molecule a much more basic character and showed better sensitivity in the PI mode. Tables 2 and 3 show the calibration data and detection limits for the studied dyes obtained with LC/ESP/MS and LC/APCI/MS in the PI mode. Figure 4 shows the LC/MS traces using LC/APCI/MS (in PI and NI mode) and LC/ISP/MS interfaces. Poor sensitivity, lower than 20–50 times, in less volatile disulfonated azo dyes versus monosulfonated dyes were reported in previous studies\(^{22}\). A better nebulization in the interface described by Rafols and Barceló\(^{14}\) was attributed to the differences. The sensitivities of disulfonated dyes were lower than those of monosulfonated ones by a factor of 10 for ISP in both studies\(^{14,22}\).

Ballantine et al.\(^{23}\) found that amine bases sensitize sulfonated azo salts towards ESP/MS. This has the effect of increasing the intensity of these ions by one to two orders of magnitude. It is proposed that the base enhances the removal of associated cations. This combines any ion peak series (from the different number of removed cations) into a single acid ion peak for each charge state \((z)\), i.e. only the \([M - nNa + (t + z)H]/[z]\) ions would be observed. Once all cations have been removed, protons may associate with the compound to balance the removal of positive charges. The number of protons observed to associate with an ion depends on the final overall ion charge \((z)\). The cation removal is not fully understood, but is thought to be influenced by the gas-phase proton affinity.

A relevant study was published by Lee and Henion\(^{24}\). They used thermally assisted ESP to detect a hexasulfonated dye (Direct Red 80) of molecular weight 1240. The mass spectrum showed only multiply charged ions ranging from \([M - 6H]^6-\) to \([M - 2H]^2-\). They also worked on the determination of several polysulfonated azo dyes\(^{25}\) by LC/ISP/MS which produced abundant \([M - Na]^+\) and \([M - 2Na]^2-\) ions with good sensitivity according to the number of sulfonic acid substituents.

In summary, the use of ESP in the NI mode offers higher sensitivity for sulfonated azo dyes than other techniques, e.g. APCI. Although APCI achieves more fragmentation, negative ESP ionization offers enough structural information which can be obtained either by increasing the extraction voltage or by using MS/MS.

3 CAPILLARY ELECTROPHORESIS

Analytes for CE include ionic compounds and nonvolatile analytes such as dyes, especially those that are not
amenable to GC and that offer problems with LC separations, such as certain dyes. Nonvolatiles of interest in the environment include ecological indicators of stress or health, biomarkers of exposure, and surfactant molecules whose metabolites act as hormone modulators that can affect wildlife and humans. A closed-circle dilemma derives from the knowledge that many of these compounds are not regulated, and therefore there is no urgent need for their monitoring. Conversely, such compounds are not monitored only because effective methods for their identification and quantitation do not exist. A partial resolution to this circle is to develop research methods for these problematic compounds to assess their occurrence, action, and fate in the environment. Such data would ultimately serve as the basis for regulation and risk reduction. Sulfonated dyes are not regulated and the use of CE can be of help in developing a routine analytical technique for monitoring them.

Recent applications of CE in the analysis of dyes are discussed here.

3.1 Capillary Electrophoresis/Ultraviolet Detection

In general, CE separation is based on the different electrophoretic mobilities of ions, and can be influenced by several parameters, e.g. pH and electrolyte concentration. In the case of dyes, the separation is often difficult to accomplish by varying the pH because they may have moieties that are strong acids. Therefore, two methods have been applied to adjust the electrophoretic mobility for the separation of six sulfonated azo dyes and other related compounds. Complexation by bis-tris propane (BTP) and interaction with linear polymers added to the buffer and acting as pseudophases were performed. A buffer system based on BTP containing poly(ethylene glycol) (PEG) and polyvinylpyrrolidone permitted the separation of all analytes. Retention of the dyes caused by the polymeric additives was related to the analyte structure. It was demonstrated that the relative decrease in the electrophoretic mobility of the dyes correlates with the number of benzoaromatic rings in the molecules. Other buffers with different micellar agents, e.g. borate at pH 8.3 with cholic acid, were employed for the determination of several sulfonated azo dyes and other classes of compounds. Analysis using SPE of spiked water samples and recovery studies were also carried out. Burkinshaw et al. used a micellar buffer system consisting of 10 mM Na₂B₄O₇ and 40 mM sodium dodecyl sulfate (SDS) at pH 9 to separate two sulfonated azo dyes with very similar structures and relative molecular weights, and also several anionic and cationic dye intermediates which could not be separated by a conventional buffer. Suzuki et al. also used 10 mM SDS as micellar agent in a mixture of 25 mM sodium phosphate buffer and 25 mM sodium borate buffer (1:1) at pH 8.0 for the analysis of sulfonated azo dyes and xanthene dyes used as food additives in Japan. However, the isomeric dyes R-2 and R-102 were not separated with good resolution, and β-cyclodextrin instead of SDS was added to achieve a good separation. Although most of the authors reported that separation of dyes by free capillary zone electrophoresis (CZE) is not possible and micellar electrokinetic capillary chromatography (MEKC) has to be applied, in some cases these compounds have been successfully separated by CZE.

Quantification studies were also done by Liu et al. using a CZE method for the separation of six synthetic food colorants including four sulfonated azo dyes and one arylmethane dye. A linear relationship between the standard concentration and peak area (PA) of each of these dyes was obtained in the concentration range 2–50 ppm, with a correlation coefficient >0.995. The relative standard deviation (RSD) of the method was about 3% and the minimum detectable amount at a signal-to-noise ratio (S/N) of 3 for all six synthetic colorants was 5 ppm.

Calibration graphs for standard solutions of eight sulfonated azo dyes and for extracted groundwater samples spiked with the same compounds were also obtained by Schönsee et al. Additionally, to evaluate the performance of the automated off-line SPE/CE/UV method, groundwater samples were spiked with mixtures of the eight dyes in the range 0.05–0.25 mg L⁻¹. The preconcentration procedure was carried out with a volume of 300 mL in order to achieve a calibration range from 10 to 50 mg L⁻¹. The LODs for the dyes ranged from 11 to 300 ppb. The regression equations were characterized by correlation coefficients >0.95, and better LODs could be calculated, for a S/N of 3, for concentrations between 10 and 150 µg L⁻¹. Figure 5 shows the separation of the target compounds in spiked groundwater (3 mg L⁻¹); after off-line SPE, this allows the determination of all the dyes.

Detection limits between 11 and 300 ppb for 11 synthetic food colorants (including some sulfonated azo dyes) were achieved using CZE with the host–guest complexation effects of β-cyclodextrin. A 300 µm i.d. capillary tube made of fluorinated ethylene–propylene copolymer in a hydrodynamically closed separation compartment was used for the analysis, accommodating 90-nL sample injection volumes, thus providing the above-mentioned detection limits. This CZE procedure was applied to several samples including a soft drink concentrate.

CE is especially useful for analyzing certain reactive dyes that HPLC often has difficulty in analyzing, such as the bifunctional β-sulfatoethylsulfone reactive dyes...
and the phthalocyanine-based dyes. CE was employed in testing the purity of reactive dye samples, monitoring the reactions (kinetic studies) of reactive dyes with nucleophiles, or analyzing colored effluents. A variety of buffers were investigated and the optimum was found to be acetonitrile at a ratio of 1:9 in a micellar buffer system (10 mM SDS, 10 mM sodium tetraborate, and 6 mM potassium dihydrogenphosphate at pH 9.0). Detection was effected with an on-line ultraviolet/visible (UV/VIS) detector positioned at the cathode. A CZE method with UV detection was developed for screening samples the majority of the peaks could not be assigned to any known compound and it was concluded that it would be necessary to couple CE with MS.

3.2 Capillary Electrophoresis/Mass Spectrometry
A comparative study of capillary liquid chromatography (CLC) and CE on the separation of some sulfonated and other classes of dyes has been carried out.[37] MEKC provided excellent separation and quantification of synthetic dyes and was found to be complementary to reversed-phase CLC in the separation and in their ability to quantify and identify analytes. Recovery data for water and soil extraction were obtained by MEKC/UV detection. Although CLC was coupled with continuous-flow liquid secondary ion mass spectrometry (CFLSI/MS) for confirmation purposes, interfacing CE with the MS instrument using a coaxial arrangement as used in CLC was more difficult and only UV detection with CE was performed.

Ion evaporation appears to be the preferred ionization mechanism for on-line CZE/MS because separated components already exist as charged species in the CZE buffer. Furthermore, this ionization process is best-suited for species which exist as ions in solution, such as sulfonated azo dyes.

Continuous-flow (CF) FAB has been coupled to CE[38] with a coaxial interface to analyze aromatic sulfonic acids and some azo dyes. However, excessive band broadening and loss of separation efficiency occurred owing to the long transfer line to the FAB ion source and the high-vacuum requirements. The newly developed atmospheric pressure interfaces such as ISP produce a mild form of ionization described by Thomson and Iribarne;[39] it was first coupled to CE by Henion et al.[40,41] with a liquid-junction interface for determining sulfonated azo dyes. Detection limits range from high parts per billion to low parts per million. The correlation coefficient for the linear regression through the means of four levels of concentration of the dye injected was found to be 0.990 and the reproducibility for automatic injection could routinely be within 2–4%. The mass spectra of the azo dyes gave peaks [M – nH]+, depending on the number of sulfonic groups. CE tandem mass spectra of the deprotonated molecular parent ion showed a daughter ion at m/z 80 corresponding to the sulfonated ion. Three sulfonated azo dyes were detected at low parts per million in spiked wastewater extract monitoring the sulfonate ion at m/z 80.

Eight mono- and disulfonated azo dyes have recently been analyzed with a Beckman P/ACE CE system connected with a Micromass interface to a VG Platform MS instrument.[42] Spiked and extracted water samples were separated and determined for confirmation of the studied compounds and a typical chromatogram of the analysis of an extracted sample is shown in Figure 6. Water samples were analyzed at the 3 ppm level by monitoring one ion for each studied compound in order to achieve maximum sensitivity. Detection limits between 100 and 800 ppb were achieved, with the exception of Acid Red 73, which exhibited low response and could not be quantified. Compounds which co-eluted and were not resolved could be determined because ions with different m/z ratios were obtained. The spectra obtained...
by CE/MS were similar to those obtained with ISP ([M − tNa + (t + z)H] ions, depending on the number of sulfonated groups (n) and the charge (z), and some losses of SO₃⁻ and COO⁻ groups). In a previous study in the same laboratory, the spectra of one of the studied dyes were compared using both interfaces (Figure 7).

In summary, CE offers good resolution and better efficiencies than LC; the use of MEKC gives a wide variety of separations of components. This enables one to analyze neutral compounds in addition to strong acids and very polar compounds that are not amenable to GC or LC. However, further optimization is required when coupling CE with MS. Detection limits are less satisfactory than those obtained using LC/MS interfaces because of the low CE injection volumes.

**4 SAMPLE HANDLING**

Nielen has reviewed sample handling which included SPE from aqueous matrices containing acidic herbicides for analysis by CE. SPE has been used for preconcentration and cleanup of sulfonated azo dyes by several authors. Brumley and Brownrigg extracted two sulfonated azo dyes (mono- and polysulfonated) and several aromatic-containing organic acids by means of Empore poly(styrene–divinylbenzene) (SDB) extraction disks and SPE cartridges (SCX cartridges). Spiked water samples were extracted by SDB disks, eluted in two ways (with organic aqueous solvent and with an ion-pairing agent) and the fractions obtained, were passed through the SCX cartridge. Extractions of solid samples were carried out by either sonification or Soxhlet methods; subsequently, the extracts were treated like the water samples. The recovery for the polysulfonated dye Triptan Blue from soil was only about 28% and was attributed to the complex structure of the dye. From water, this compound showed higher recoveries. In contrast, the monosulfonated dye Orange II could be extracted with good recoveries from both water and soil samples.

Other types of solid phases have been employed for sulfonated dyes, such as C₁₈ cartridges and columns that were eluted with aqueous organic solvents. C₁₈ cartridges

from J.T. Baker, which were eluted with solvent mixtures of methanol–water–triethylamine (TEA), gave recoveries that ranged from 87 to 103% for monosulfonated azo dyes and from 65 to 105% for disulfonated azo dyes.\(^{22}\) With the C\(_{18}\) columns from J.T. Baker, eluted with methanol after preconditioning with ammonium acetate buffer, recoveries that ranged from 70 to 122%\(^{25}\) were achieved.

The application of copolymers such as SDB was found to be most suitable for the SPE of very polar...
Cross-linked polymeric sorbents with sulfonic functions, such as Isolute ENV+ and LiChrolut EN, were examined for their suitability for off-line preconcentration of the studied sulfonated azo dyes. The recovery and standard deviation data obtained on processing 300 and 500 mL of spiked groundwater samples are reported in Table 4. Preconcentration with Isolute ENV+ using 100% MeOH (0.01%TEA) as eluent achieved recoveries up to 71%. The application of Isolute ENV+ for further optimizations was found to be more effective. Although the recoveries of Acid Yellow 23 and Acid Blue 113 were below 50%, for six dyes the recoveries could be improved to 64–83% by eluting with a mixture of 80% MeOH, 20% water, and 0.2% TEA.

More sorbents should be tested for extraction and preconcentration of dyes in various environmental water matrices. Polymeric sorbents with different polymer functionalities, e.g. sulfonation, seem to work better than silica-based phases. The development of immunoaffinity sorbents may lead to a solution to the problem of low recoveries for some of the more polar and ionic dyes. In general, it would be necessary to find sorbents that allow the percolation of large volumes of up to 1–2 L in order to reduce the LODs of CE techniques.

5 CONCLUSIONS

LC/MS has been shown to be a good method for the determination of dyes. In this respect TSP has worked well for several classes of these compounds, but it has shown poor sensitivity for sulfonated azo dyes. Some techniques were applied to improve the detection limits of these compounds, such as the use of a wire repeller or restricting the vaporizer exit, but the development of LC/API/MS interfaces, which provide more structural information and high sensitivity, can lead to more extensive use in environmental analysis.

replacing classical LC/MS interfaces. In particular, ISP can provide, with the manipulation of the cone voltage or combination with MS/MS, enough structural information and selectivity.

CE, with its different modes, shows several advantages for polar analytes and can be easily coupled with classical ESP interfaces because of the restricted flow rates. Sensitivity problems result from the small injection volumes and, therefore, preconcentration techniques should be applied. Limits of detection for the various techniques reported in this paper are shown in Table 5. More work needs to be done in the future and the focus will likely be towards the application of CE/MS combined with SPE. Owing to the high efficiency and diversity of separation in CE, and the fact that it is inexpensive and a low generator of waste, the technique will permit the required analytical performance for determining sulfonated azo dyes in environmental waters to be achieved.

The interest in analytical procedures for explosives residues in environmental media steadily increases as more and more formerly utilized military sites are certified and converted to full- or part-time civilian use. Careful statistical studies have clearly demonstrated that analyses based on randomly collected “grab” samples of soils frequently produce a false picture of the extent of explosives contamination. Well-designed sampling plans, which
employ multiple samples taken from small areas and which consider the distribution of the soil particles, are mandatory for understanding the true extent of contamination. Because site remediation is such a costly venture, there is a strong need for analytical procedures which are capable of quantitating explosives in soil and groundwater samples quickly and accurately, using equipment and methods which may be operated reliably by nontechnical personnel. For that reason, scientific interest is gradually moving away from the completely laboratory-based, statistically validated, and highly technical standardized methods, such as high-pressure liquid chromatography (HPLC) and gas chromatography (GC) and their mass spectroscopic analogs, towards the many fieldable analytical techniques. Some of these, such as ion mobility spectrometry and the various magnetic resonance techniques, are still in their infancy; their potential and utility are still to be fully developed. Others, such as the colorimetric and enzyme-based field test kits, have been fully tested and, in some cases, have been adopted as standard methods themselves. Still others, such as the various mass spectrometric methods, involve highly technical equipment which must be simplified before it can be used routinely in the field. However, the extreme sensitivities characteristic of these state-of-the-art instruments partially offset the need for extensive operator training. A variety of mass spectrometric techniques may yet be used routinely for explosives residue analysis in the field. Some of these new methods may be used in, or even be derived from, forensic applications.

1 INTRODUCTION

1.1 Chemical Classes of Explosives

Nitrogen-containing explosives and their transformation products detected in the environment are almost always of military origin and fall into three distinct classes. The nitroaromatics are related to 2,4,6-trinitrotoluene (TNT, CAS 118-96-7), and include the following species: 1,3,5-trinitrobenzene (1,3,5-TNB, CAS 99-35-4); 1,3-dinitrobenzene (1,3-DNB, CAS 99-65-0); methyl-2,4,6-trinitrophenyl nitramine (tetryl, CAS 479-45-8); 2,4-dinitrotoluene (2,4-DNT, CAS 121-14-2); 2,6-DNT, (CAS 606-20-2); 2-amino-4,6-dinitrotoluene (2-Am-DNT, CAS 33572-78-2); and 4-amino-2,6-dinitrotoluene (4-Am-DNT, CAS 19406-51-0). The nitramines, which are more energetic than the nitroaromatics, include the two heterocyclic compounds hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX, CAS 121-82-4) and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX, CAS 2691-41-0). The nitrate esters are represented by nitroglycerine (NG, CAS 55-63-0) and pentaerythritol tetranitrate (PETN, CAS 78-11-5). The physical properties of these species are summarized in Table 1[1,2,3] while their structures are presented in Figure 1. The chemical names and common acronyms of additional explosives have been tabulated in Beveridge.[4]

Ammonium picrate (ammonium 2,4,6-trinitrophenoxide, CAS 131-74-8 AP) was the principal explosive used in a number of armor-piercing shells, bombs, and rocket warheads from the early 1900s until after World War II. While AP is no longer manufactured, wastes containing this component are still encountered at military installations in the United States. Picric acid (2,4,6-trinitrophenol, CAS 88-89-1 PA) is both an explosive and a common industrial chemical with uses that include dyeing fabric and leather, glass coloration, and metal etching.[5]

The scope of this review focuses on the analysis of organic explosives in the environment. A discussion of the properties and determination of the inorganic explosives, such as water gels and ammonium nitrate fuel oil, has been omitted intentionally.

1.2 The Origin of Explosives in Contaminated Soil

The contamination of soil with explosives frequently resulted from historical – and now both outdated and unapproved – disposal practices from manufacturing, spills, ordnance demilitarization, lagoon disposal of explosives-contaminated wastewater, and open burn/open detonation (OB/OD) of sludges from explosives processing, waste explosives, excess propellants, and unexploded ordnance. Facilities that may be contaminated with explosives include active and former manufacturing plants, ordnance works, army ammunition plants, naval ordnance plants, army depots, naval ammunition depots, army and naval proving grounds, burning grounds, artillery impact ranges, explosive ordnance disposal (EOD) sites, bombing ranges, firing ranges, ordnance test and evaluation facilities, etc. A number of these facilities have high levels of soil and groundwater contamination, although waste disposal was discontinued 20 to 50 years ago. Common munitions fillers and their associated secondary explosives include Amatol (ammonium nitrate/TNT), Baratol (barium nitrate/TNT), Cyclonite or Hexogen (RDX), Cyclotolts (RDX/TNT), Composition A-3 (RDX), Composition B (TNT/RDX), Composition C-4 (RDX), Explosive D or Yellow D (AP/PA), Octogen (HMX), Octolts (HMX/TNT), Pentalite (PETN/TNT), Picratol (AP/TNT), Tritonal (TNT), Tetrytolts (tetryl/TNT), and Torpex (RDX/TNT).[6] The United States has characterized 30 large and medium sized TNT-contaminated sites at federal facilities; together, they contain over one million cubic yards of contaminated soil. The total number of smaller sites contaminated with TNT is not yet known.

but it is reported that the army alone has on the order of 2000 explosive-contaminated sites that may require remediation, and more exists at navy and air force facilities. Similar patterns of contamination are found throughout Europe and the former Soviet Union. Evaluating sites potentially contaminated with explosives is necessary to carry out US Department of Defense, United States Environmental Protection Agency (USEPA), and US Department of Energy policies on-site characterization and remediation under the Superfund, Resource Conservation and Recovery Act (RCRA), Installation Restoration, Base Realignment and Closure (BRAC), and Formerly Utilized Defense Site (FUDS) environmental programs.
1.3 The Origin of Explosives in Contaminated Groundwaters

Groundwater may be contaminated with explosives in two distinct ways. The first is a direct consequence of the disposal of munitions wastes during World War I, World War II, the Korean War, and the Viet Nam War. Unlined lagoons, which could not contain species such as munition charges, were frequently employed. Leached mobile contaminants migrated with groundwater at several installations. The second involved the disposal of washwaters used to clean equipment and interior surfaces at munition manufacturing and demilitarization facilities. It has been estimated that up to $2 \times 10^6$ L of this type of wastewater is generated daily from a single production line. Current practice is to collect washwater from these processing operations in a holding tank and periodically pump it through a series of carbon adsorption columns prior to discharge to surface streams. Standard practice allows monitoring of explosives concentrations between columns to prevent contamination downstream. These point discharges are subject to state and federal National Pollutant Discharge Elimination System (NPDES) permits that generally limit the acceptable concentrations of TNT and RDX. Although carbon adsorption technology can reduce TNT and RDX to low part per billion levels, these carbon columns have finite lifetimes. Eventually, breakthrough occurs and regeneration or replacement is necessary. Ground- and surface-water contamination may therefore occur immediately prior to replacement of the carbon adsorption water treatment columns.\(^{(19)}\)

1.4 Regulatory Limits for Explosives in Groundwater and Soil

The USEPA, in collaboration with the Oak Ridge National Laboratory, has published a series of health advisories and recommended water criteria for several explosives-related chemicals, as summarized in Table 2.\(^{(2,3,10)}\) These values for the nitroaromatics range over two orders of magnitude between 2,6-DNT (0.0068 $\mu$g L$^{-1}$ water)\(^{(11)}\) to TNT (1.0 $\mu$g L$^{-1}$ water).\(^{(12)}\) If the criterion for HMX (400 $\mu$g L$^{-1}$ water)\(^{(13)}\) is also included, the range spans four orders of magnitude. The criteria for 2,4-DNT (0.17 $\mu$g L$^{-1}$ water),\(^{(11)}\) RDX (2.0 $\mu$g L$^{-1}$ water)\(^{(14)}\) and 1,3,5-TNB (1.0 $\mu$g L$^{-1}$ water)\(^{(15)}\) are intermediate. No general recommendations have been issued for contaminant levels in soil. Instead, soil levels have been evaluated on a site-by-site basis, depending on such factors as the proximity of the contaminated soil to locations of groundwater use. For example, at Cornhusker Army Ammunition Plant, cleanup criteria of 5 $\mu$g TNT g$^{-1}$ soil, 10 $\mu$g RDX g$^{-1}$ soil, and 15 $\mu$g TNB g$^{-1}$ soil were established.\(^{(16)}\)

To compound the problem of toxicity, explosives are remarkably persistent in the environment when they are initially present at elevated concentrations. A study was performed at Los Alamos National Laboratory to determine the half-lives of various explosives in the soil in a temperate climate.\(^{(17)}\) The samples contained 0.1% w/w of one of twelve explosives mixed with soil in a blender. Samples were then placed in transite cylinders with fine-mesh stainless steel screen

\(^{a}\) Plastic-bounded explosive.
on the bottom and hardware cloth over the top, then buried in the test area outdoors with their tops flush with the surrounding surface. The explosives were therefore subjected to naturally occurring temperature fluctuations, rainfall, and bacterial decomposition over a period of twenty years. Estimates of the half-lives were made from normalized ultraviolet (UV) chart data by applying first-order rate equations. The results of these tests are summarized in Table 3, and demonstrate that the half-life of various explosives in soil can range between 1 year (for TNT) to 92 years (for PETN). The half-lives of plastic-bonded explosives exceed 100 years.

It should be emphasized that the Los Alamos results applied to (a) very substantial concentrations of explosives which were (b) mixed artificially with soils to create samples. Other investigators have emphasized that the degradation behavior of low concentrations of explosives in contaminated soils found in the environment frequently exhibits a strikingly different behavior. For example, Rodacy et al. exposure small masses of authentic contaminated soil samples containing 10 ppb TNT or RDX in shallow dishes to sunlight outdoors. The concentration of TNT was undetectable after 60 days, while that of RDX was essentially unchanged. Observations such as these suggest that the degradation of low concentrations of explosives such as TNT in soil may proceed by mechanisms other than first-order kinetics. Special handling may be needed to assure that such concentrations in soil remain stable until the sample is actually analyzed. The entire issue of determining “holding times” for explosives in soil samples is discussed in section 2.2, entitled “Maximum Holding Times (MHT) for Soil and Aqueous Samples”.

2 SAMPLING CONSIDERATIONS

2.1 Special Considerations for Soil Sampling

The traditional approach for sampling soils which may have been contaminated with explosives is to use “grab” samples, taken from a wide area. These samples would then be analyzed using appropriate field or laboratory-based procedures. The resulting data would be used to evaluate the level of explosives contamination and to choose the appropriate cleanup procedure(s). Careful thought would suggest that random grab sampling might not be the most appropriate strategy. An implicit assumption in this approach is that the distribution of contaminants is sufficiently homogeneous that the results from the analysis of these discrete samples can be used to represent average site conditions within the grid. In general, the number of discrete samples collected is insufficient to address the short-range distribution of contaminants and, practically speaking, all samples are automatically assumed to be representative of average site conditions within the grid from which they were collected. Furthermore, the environmental characteristics of explosives-related compounds in soil indicate that they are extremely heterogeneous in spatial distribution. Concentrations range from nondetectable levels (<0.5 ppm) to percent levels (>100 000 ppm) for samples collected within several feet of each other. In addition, the waste disposal practices at these sites, such as OB/OD, exacerbate the problem and may result in conditions ranging from no soil contamination up to solid “chunks” of bulk high-explosives, such as TNT or RDX. Secondary explosives concentrations above 10% (>10 000 ppm) in soil are of concern because of potential reactivity that affects sampling and materials handling processes during remediation. Often, 70–90% of soil samples analyzed during an explosives site investigation do not contain detectable levels of contamination. Jenkins et al. observed that:

Accurate chemical characterization of a hazardous-waste site requires the development and implementation of a well-designed sampling plan. After defining the area of interest [target population(s)], which might be an entire site or several defined areas within a site, samples are collected according to one of several possible schemes. Distributions of contaminants are very site specific, depending on the manner in which the contamination occurred, the physical and chemical properties of the contaminants involved, soil type, and the geology and hydrogeology of the site. Because of these site-specific characteristics, many references recommend that one perform a preliminary study before devising a sampling plan. [Reprinted by permission of John Wiley & Sons, Inc., © 1997 from T.F. Jenkins, C.L. Grant, G.S. Brar, P.G. Thorne, P.W. Schumacher, T.A. Ranney, Field Analyst. Chem. Technol, 4, 151.]

Beginning in 1996, Jenkins et al. systematically investigated the degree of short-range heterogeneity in analyte concentrations present at explosives-contaminated sites. Soil was sampled at nine locations on three installations. At each location, seven discrete grab samples were collected in a wheel pattern of radius 61 cm (one sample from the center and six equally spaced around the perimeter). Each of the seven samples was homogenized in the field and duplicates were analyzed by both an on-site colorimetric method (USEPA SW-846, Method 8515, “Colorimetric Screening Method for TNT in Soil”) as well as an off-site standard method (USEPA SW-846 Method 8330 “Nitroaromatics and Nitramines by High Performance Liquid Chromatography”) both described elsewhere in this article. Portions of the seven discrete samples were
also used to form a composite sample which was analyzed by both procedures. TNT concentrations obtained from both types of analysis varied by as much as two and a half orders of magnitude within a sampling wheel. Partitioning of overall variances for data indicated that sampling error dominated over analytical error. Therefore, the probability of collecting discrete samples that represent average analyte concentrations is very unlikely with these levels of heterogeneity. Results from analysis of composite samples, however, exhibited mean concentrations representative of the average condition, as well as low relative standard deviations (RSDs), indicating that field homogenization was adequate for characterization.

These results\(^{(20)}\) exhibit several unifying themes that can be applied in designing future investigations of explosives-contaminated sites. First, it is clear that there was extreme heterogeneity at all sampling locations. A single sample from any of the 122-centimeter diameter circles could differ by orders of magnitude or more from the mean concentration of the small area sampled. RSDs for the seven discrete samples were often greater than 100%. A second consistent finding was that composite samples of the seven discrete samples could be reliably homogenized and subsampled on-site. This also opens the possibility of compositing discrete samples representing a larger area if concentration variations suggest that this approach would be desirable. Most importantly, it permits on-site processing without elaborate apparatus.

Jenkins et al.\(^{(20)}\) summarized the shortcomings of the grab sampling approach as follows:

> Although random grab sampling is appealing from a cost perspective, it may be totally inadequate for decisions about the need for, or adequacy of, remediation. To provide data that can satisfy this need with a high level of confidence, the total uncertainty associated with site characterization must be understood and reduced to acceptable levels. ... For these four locations [as described in reference 20], standard deviations due to analysis, whether on-site or laboratory, were always much lower than the corresponding deviations due to sampling, and hence total error was dominated by sampling error. For the other locations, sampling error was even greater and so overwhelmed analytical error that this type of fractionation would only be possible with the use of asymmetric (here, logarithmic) limits. Clearly, if we want to make a significant improvement in the quality of site-characterization data, the major effort should be placed on reducing sampling error. Single grab samples are totally inadequate.\[Reprinted by permission of John Wiley & Sons, Inc., \(\odot 1997,\) from T.F. Jenkins, C.L. Grant, G.S. Brar, P.G. Thorne, P.W. Schumacher, T.A. Ranney, \textit{Field Anal. Chem. Technol.}, 1, 159.\]

The results presented above needed to be expanded by evaluating additional explosives, sites, and sampling strategies. Jenkins et al.\(^{(26)}\) described such additional work performed on soil samples at an active firing range located at Canadian Force Base (CFB)-Valcartier, Quebec. The principal contaminant, HMX, was present at concentrations about two orders of magnitude greater than TNT, even though the munition fired at this site had a 70:30 ratio of HMX to TNT. The authors again observed that sampling error frequently exceeded analytical method error by at least tenfold, and that more precise analytical results would be obtained only when more representative samples were taken. Several approaches were recommended to address this problem, such as on-site homogenization, compositing of discrete samples, and on-site analysis with appropriate confirmation results at an off-site environmental laboratory.

Additional work which evaluated the effect of sampling depth and novel sampling patterns was performed at the Ft. Ord, CA, firing range.\(^{(27)}\) The contamination at Ft. Ord, like that at CFB-Valcartier, originated from antitank rockets. Hence, the contamination was not random. Depth profiling was performed using manual excavation for 0–15, 15–30, 30–45, and 45–60 cm, and a post-hole digger for 105–120 cm. Analysis of these soils showed that by far the greatest concentration of HMX was in the 0–15 cm depth range, with minimal penetration to lower levels. The authors also noted that the vast majority of explosives contamination was centered near the tank targets, rather than being distributed uniformly or near-uniformly throughout the site. The investigators observed:

> Since much of the site is free of significant explosives residue, it is inappropriate to estimate a mean concentration for a large area. Instead, sampling should concentrate on surface soils around target locations, to define the boundaries of contamination. To demonstrate this point, the concentrations of HMX in surface soils were plotted as a function of distance from the target along with similar data from CFB-Valcartier. With concentrations decreasing as distance from the target increases, a logical sampling strategy would use concentric rings with the target at the center. Such rings might employ radii varying by 3 to 5 m. Eight or more sample points would be located equidistant from each other around each ring, which would allow two composite surface samples to be formed for each ring. Each discrete sample should contain about a kilogram (±200 g) of soil and be homogenized thoroughly prior to subsampling for formation of composites. Each composite would contain one-half of the sampling points chosen in an alternating pattern. Results of this work demonstrate that EOD personnel can efficiently collect soil samples for site characterization at the same time that they are clearing the site for unexploded ordinance. Since the major portion of the explosives residues at the inland ranges are in the surface soils, samples for additional characterization should be relatively easy to collect. The depth of contamination in specific areas can be determined iteratively after the extent of surface contamination is mapped.\[Reprinted by permission of the Cold Regions Research and Engineering Laboratory from T.F. Jenkins, \textit{Field Anal. Chem. Technol.}, 1, 159.\]
An unexpected observation from the Ft. Ord study was the effect of very small particles on bulk measured concentrations of HMX. A large amount of fine dust was noted when very dry bulk samples were homogenized and subsampled. Analysis of two samples of dust showed HMX concentrations two to three times higher than that for the bulk soil. Apparently, a substantial portion of the explosives residues are associated with very fine particles that are not bound to the bulk sands. Clearly, there is danger of loss of these fine particles during mixing and subsampling.

2.2 Maximum Holding Times for Soil and Aqueous Samples

The “MHT” is the longest interval that a sample, aqueous or soil, may be stored prior to analysis before its analyte concentration is reduced by an unacceptable level or percentage. USEPA procedures specify a maximum pre-extraction holding time of seven days at 4 °C in the dark, to be consistent with the MHT values of other organics in soil. One study described the determination of the MHT in uncontaminated soils and aqueous matrices. The soils were taken from three totally unrelated sources, viz. (a) standard soil obtained through the US Army Toxic and Hazardous Materials Agency; (b) Captina silt loam from Roane County, TN; and (c) McLaurin sandy loam from Stone County, Mississippi (MS). Similarly, the aqueous samples were also drawn from three independent sources, viz.: (a) reagent-grade water; (b) groundwater from the Oak Ridge National Laboratory Aquatic Ecology Facility; and (c) surfacewear from the headwaters of White Oak Creek on the Oak Ridge Department of Energy Reservation. Aliquots of soil or water were spiked with explosives as required, then stored and analyzed as described in the reference.

The two statistical definitions used to determine the MHT were specified by the American Society for Testing and Materials (ASTM) and Environmental Science and Engineering, Inc. (ESE) for a holding time study conducted in co-operation with the USEPA. Both definitions are based on an approximating model for predicting concentration with time. The ASTM defines the MHT as the time the predicted concentration falls below the lower two-sided 99% confidence interval on the initial concentration. The ESE defines the MHT as the time the one-sided 90% confidence interval on the predicted concentration falls below a 10% change in the initial concentration. The difference between the two definitions is the method of placing a lower bound on the initial concentration. The ESE MHTs are usually longer than the ASTM MHTs because decreasing the initial concentration by 10% is usually a larger reduction than the lower two-sided 99% confidence limit. The ASTM MHT definition is recommended for analytical methods with precision such that the lower bound on 99% confidence limit for an analyte concentration is less than 10% of the initial concentration. Otherwise, using the ESE MHT definition would be more conservative. The results of the study on MHT for four explosives in both aqueous and soil matrices are summarized in Table 4; the calculated MHT are all considerably longer than those recommended by the USEPA.

Grant et al. provided additional MHT values not only from dry spiked soil, but also authentic contaminated soils from the Rockeye site at the Naval Surface Warfare Center (NSWC) at Crane, IN. The latter soils contained measurable concentrations of HMX, RDX, TNT, and TNB, two isomeric microbiological transformation products of TNT, viz., 2-Am-DNT and 4-Am-DNT, and 3,5-dinitroaniline (3,5-DNA), a microbiological transformation product of TNB. The blank soils employed in this study were obtained from Windsor (VT), Charlton (NH), and Ft. Edwards (NY). All soils were spiked with explosives dissolved in water to eliminate any acetonitrile effects. The results on spiked soils showed that RDX and HMX are stable for at least eight weeks when refrigerated (2 °C) or frozen (−15 °C) but that significant transformation of TNT and TNB can occur within two hours without preservation. Freezing provides adequate preservation of spiked 2,4-DNT for eight weeks or longer. The results on field-contaminated soils did not show the rapid transformation of TNT and TNB that was observed in the spiked soils, and refrigeration appeared satisfactory.

*a Immediate freezing recommended.*
Presumably, the explosives still present in the field soil after many years of exposure are less biologically available than in the spiked soils. (6) An earlier related study (33) demonstrated that explosives in spiked, air-dried soils are stable for a 62-day period under refrigeration. Data from the Grant et al. (32) study indicate that air drying of field-contaminated soils may not result in significant losses of explosives contaminants. Explosives in air-dried soils are stable at room temperature if they are kept in the dark.

Most of the analytical procedures for explosives in soils employ acetonitrile extracts, which are expected to be stable for at least six months under refrigeration. Acetonitrile extracts are also thought to be stable if they are stored in the dark under refrigeration. The latter solvent is normally not recommended because it enhances the photodegradation of explosives. (6)

3 DETERMINATION OF EXPLOSIVES IN AQUEOUS SAMPLES

3.1 Procedures Employing “Salting-out” Liquid–Liquid Extraction Followed by High-pressure Liquid Chromatography

The most traditional extraction procedure for isolating explosives from aqueous samples involves the liquid–liquid extraction of the sample with a nonpolar solvent such as dichloromethane. Leggett et al. (34) evaluated this approach critically and proposed a superior alternative based on “salting-out” the explosives from a sample. Briefly, 130 g of sodium chloride was dissolved in 400 mL aqueous sample, to which 100 mL acetonitrile was then added. After the mixture was shaken vigorously in a separatory funnel, the layers were allowed to separate. Under these conditions, the final volume of immiscible acetonitrile was 22 mL, allowing a preconcentration factor >16. Individual component recoveries for a wide variety of nitroaromatics, nitroesters, and nitramines ranged between 93 and 100%. The authors confirmed that recoveries were not dependent on analyte concentration over at least a 200-fold range in concentration, and the presence of chloride in the acetonitrile phase had no effect on analyte retention times (see below).

The most widely-used method for separating and detecting extracted explosives employs HPLC with UV absorbance detection at 254 nm. The analytes are separated on an octyl (LC-8, 25 cm x 4.6 mm, 5 µm particles, product of Supelco, Inc., Bellefonte, PA) column using a water–methanol–acetonitrile (50 : 38 : 12 v/v/v) eluent (1.5 mL/min flow rate). Such a configuration permitted the major target analytes, viz. HMX, RDX, TNT, and 2,4-DNT, to be separated from the following species: TNB; SEX (1-acetylactahydro-3,5,7-trinitro-1,3,5,7-tetrazocine, CAS 13980-00-2); TAX (1-acetyhexahydro-3,5-dinitro-1,3,5-triazine, CAS 14168-42-4); 2,6-DNT; 2-Am-DNT; 4-Am-DNT; 2,6-diamino-4-nitrotoluene (2,6-Dam-NT, CAS 59229-75-3); 2,4-diamino-6-nitrotoluene (2,4-Dam-NT, CAS 6629-29-4); and 2,4,5-TNT. (10) When a typical 100 µL sample injection was employed, the detection limits were 26, 22, 14, and 10 µg L−1 for HMX, RDX, TNT, and 2,4-DNT, respectively. These values were initially calculated using three times the standard deviation of the detector baseline noise, and were later confirmed using formal calculations based on the method of Hubaux and Vos. (35) Such calculations employ not only replication but also user-specified estimates of both false-positive and false negative errors (typically 5% for each). This analytical procedure was later modified to employ a methanol–water (1:1) eluent with the same flow rate. A related confirmation procedure employed a bonded cyano HPLC phase (LC-CN) column (25 cm x 4.6 mm, 5 µm particles, Supelco) with identical mobile phase, flow rate, detector, and monitoring wavelength. The two aforementioned separations provide almost exactly opposite analyte retention orders, resulting in a powerful tool for analyte identification.

The HPLC-based procedures described above were validated using a collaborative study involving nine independent laboratories. (36, 37) The four test matrices employed represented uncontaminated, treated, fortified, and authentic contaminated matrices. Based on the overall excellent performance of the HPLC procedures, they were ultimately adopted as standard methods for the analysis of nitroaromatic and nitramine explosives in water by the Association of Official Analytical Chemists (AOAC) and the USEPA, and in soil by AOAC, ASTM, and the USEPA. (1, 28)

The HPLC methods described above may be modified slightly to enable either improved separation of specific analytes or improved reliability of identification. For example, two pairs of aminodinitrotoluenes (2-Am-DNT and 4-Am-DNT) and dianaminitrotoluenes (2,4-Dam-NT and 2,6-Dam-NT) cannot be resolved using the LC-CN column alone. However, all constituents may be baseline resolved by using two columns, viz., a short octadecyl column (LC-18, 3.3 cm x 4.6 mm i.d., 3 µm particle size, Supelco) and a traditional cyano column (LC-CN, 25 cm x 4.6 mm i.d., 5 µm particle size), placed in series. The separation employs a ternary eluent (water–methanol–tetrahydrofuran, 60.5 : 25 : 14.5 v/v/v) with a flow rate of 1.5 mL min−1 (38). The use of HPLC in combination with photodiode-array detection is advantageous, because peak identification is more reliable with additional information from the UV spectrum. Further, by comparison of the various UV spectra at the peak front edge, peak apex, and peak end edge, one
can determine whether a single component is, indeed, present, or whether contaminants are co-eluting with the analyte of interest. Emmrich et al.\textsuperscript{(39)} studied the separation of 21 nitroaromatics and nitramines in a single run using HPLC and reported both absorbance maxima \(\lambda_{\text{max}}\) and the molar absorptivities \(\epsilon_{\text{max}}\) for each analyte. The authors used a Merck LiChrospher 100 RP-18 column (25 cm x 4 mm i.d., 5 \(\mu\)m particle diameter) and mobile phases employing (a) methanol–water (1:1 v/v, isocratic elution), (b) methanol–water gradient elution, or (c) methanol–water containing 2% v/v tetrahydrofuran, gradient elution. All analytes were eluted and resolved using the gradients, but TNT and nitrobenzene (NB) almost co-eluted. The presence of a small volume of tetrahydrofuran enabled these two particular analytes to be resolved cleanly. The HPLC method of Caton and Griest\textsuperscript{(40)} was developed to quantitate the transformation products of TNT which would be observed during composting. This procedure uses an RP-C\textsubscript{18}/Anion Mixed-Mode reverse phase/anion exchange column and three eluents: (a) 90:10 water–methanol v/v solution that was 0.015 M in potassium phosphate; (b) methanol; (c) acetonitrile. Two independent gradient programs were developed and evaluated. Quantitations were performed employing the UV absorbance at 254 nm. The aminonitrotoluenes were baseline-resolved successfully using a single column.

### 3.2 Procedures Employing Solid-phase Extraction

The “salting-out extraction” (SOE) procedures described above were clearly successful for removing and concentrating explosives from aqueous samples, but they also exhibited several distinct disadvantages. First, each extraction generated a considerable volume of chemically hazardous waste. Second, liquid–liquid extractions in general may produce emulsions which may or may not clear easily with time. Third, concentration factors greater than approximately 25 would be difficult to achieve without either substantial volume reduction of the acetonitrile extract or the use of very large (>2 L) aqueous sample volumes. The extraction of such large sample volumes using traditional liquid–liquid extraction glassware becomes unwieldy. Taken together, it is worthwhile considering procedures based on solid-phase extraction (SPE), where the aqueous sample passes through a small cartridge or disk containing an appropriate medium which has been conditioned with organic solvent. After the disk or cartridge is dried, the explosives are eluted with a small volume, typically not more than 5 to 10 mL, of organic solvent.

Maskarinec et al.\textsuperscript{(41)} evaluated the extraction properties of three SPE media, viz. XAD-4, Porapak\textsuperscript{R} R (vinyl pyrrolidone, Waters Corporation), and Porapak\textsuperscript{R} S (vinyl pyridine, Waters), which were packed into small columns and conditioned initially using acetone and water. Fortified aqueous samples (500 mL) were pumped through each column, and explosives were removed using 10 mL acetone under gravity flow. Acetone was exchanged for ethanol prior to HPLC analysis.

The presence of explosives was monitored using both UV and liquid chromatography/electrochemical detectors (LC/ELCD). The sensitivity of the former was approximately 1 \(\mu\)g mL\textsuperscript{-1} ethanolic extract for HMX, RDX, TNT, 2,4-DNT, and 2,6-DNT when the monitoring wavelength was 254 nm. The LC/ELCD (\(-1.0\) V vs Ag/AgCl reference electrode) had several notable advantages and disadvantages compared to the complementary UV detector. The LC/ELCD exhibited approximately tenfold better sensitivity for explosives than the UV detector.\textsuperscript{(42)} Furthermore, the detector response would be proportional to the number of nitro groups present on a given analyte. Hence, the LC/ELCD was ideal for detecting potentially unidentified by-products and transformation products of explosives with at least some selectivity. In addition, LC/ELCD was superior to the UV detector for monitoring species such as NG and PETN. These compounds absorb weakly at 254 nm and strongly at 210 nm, where substantial interferences are well-known. As a worst-case example, the estimated detection limits of NG using the UV detector (254 nm) and LC/ELCD were 160 ng and 0.38 ng, respectively.\textsuperscript{(43)} On the other hand, the LC/ELCD was considerably less robust than the UV detector. Oxygen had to be removed scrupulously from both the final ethanol extract and the eluent. The gold substrate and mercury-film electrode had to be prepared carefully and refreshed frequently due to contamination from irreversibly adsorbed species.

Overall, the two Porapak\textsuperscript{R} resins outperformed XAD-4 as an extraction medium for explosives. They behaved in a manner consistent with specific adsorption of nitro compounds, in that the breakthrough volume was nearly equivalent for the test analytes HMX, RDX, TNT, and DNT. Even SEX and TAX, two very polar explosives by-products, were retained quantitatively.

Jenkins et al.\textsuperscript{(10)} compared the characteristics of the SOE with two SPE media, viz. cartridge-based Porapak\textsuperscript{R} R and Empore\textsuperscript{R} styrene–divinylbenzene disks, both conditioned with acetonitrile and water. The data collected over a four-day evaluation period were used to calculate certified reporting limits (CRL) according to a statistically unbiased procedure.\textsuperscript{(44)} The CRL values are tabulated in Table 5. In general, none of the procedures were consistently superior to the others in low concentration detection capability. The only CRL value that appears out of line is that for tetryl determined using membrane-SPE, \(0.83\) \(\mu\)g L\textsuperscript{-1}. Inspection of the data
HMX and RDX, and experimented with new cleaning procedures to better remove interferences from these materials. As a result, Waters Corporation released a new ultra clean SPE material for use in cartridge SPE under the name Porapak® RDX (ultraclean divinylbenzene-vinylpyrrolidone), and 3M Corporation developed a new surface modified styrene divinylbenzene membrane which had also been cleaned more extensively (Empore® styrene–divinylbenzene “reverse-phase sulfonated”, or SDB-RPS). The latter is a modified phase which provided additional retention for polar organics such as HMX.

Porapak® RDX cartridges were evaluated extensively, as described in Bouvier and Oehrle. High-purity water samples fortified to 1 or 10 ppb in each of 14 explosives or explosives-related products were extracted using cartridges which had been preconditioned with acetone and water. The concentrated explosives were eluted with a small volume of acetonitrile, which was subsequently diluted to 40% with high-purity water, vortexed, and analyzed by HPLC (variable wavelength detection). The recoveries of all 14 analytes, ranging from the polar HMX and RDX to the nonpolar 2,4-DNT and 2,6-DNT, exceeded 89% with RSDs of less than 7%.

Walsh and Ranney recently and independently compared the performance of the Waters Sep-Pak Vac Porapak® RDX cartridges with Empore® (SDB-RPS) extraction membranes. The cartridges were conditioned using acetone followed by water; the membranes were conditioned with acetone, isopropanol, methanol, acetoneitrile, and finally water. After passage of each water sample through the solid-phase, air was drawn through the solid phase for 15–20 min to remove as much residual water as possible. The explosives were eluted from the solid phases with 4–5 mL acetoneitrile. Final separation and quantitation of each analyte was performed using a gas chromatograph equipped with an electron capture detector (ECD) using the specific modifications noted in the reference. The authors specifically noted that calibration curves employing linear models were not appropriate for quantitating explosives when the ECD was employed. Instead, a quadratic model with all terms statistically significant, not only was more satisfactory but also allowed a greater concentration range to be covered. Furthermore, low concentration trinitroaromatic standards were unstable even when left in amber vials at room temperature. When the autosampler tray was cooled, these concentrations were stable during a typical 12-hour shift. The average recoveries observed from the two extraction media were entirely comparable for water samples spiked to 5 and 10 μg L⁻¹ in each of nine explosives, regardless of whether gas chromatography with electron capture detection (GC/ECD) or HPLC was used as the final quantitating method, and ranged between 85 and 136% for all analytes and both quantitating methods.

- Using cartridges containing Porapak® R conditioned with acetoneitrile, then water.
- Using Empore® styrene–divinylbenzene disks conditioned with acetoneitrile, then water.
- NT, nitrotoluene.

indicated that this high CRL was caused by low recovery on only one of the four certification days. Elevated CRL values for tetryl were noted by other workers who attributed this behavior to the instability of the analyte in water. The present authors suggested that this instability is due to photochemical decomposition. The study also included the evaluation of 38 groundwater samples taken for method comparison from the Rockeye site at the Naval Surface Warfare Center (NSWC) in Martin County, IN.

Overall, the results may be summarized as follows:

- The three methods were comparable with respect to low-concentration detection capability, ranging from 0.05 to 0.30 µg L⁻¹.
- Percent recoveries generally exceeded 80% except for HMX and RDX by membrane-SPE, where recoveries were lower.
- Large interferences were found on about half of the groundwater samples from the NSWC, using the two SPE methods, but none were found by SOE.
- The SPE interferences were traced to a matrix interaction of the SPE polymers with low pH groundwaters which apparently caused the release of unreacted monomers or other contaminants from the interior of the polymer.

At least partly in response to the problems identified above, several manufacturers of SPE materials sought to improve the retention of very polar organics such as HMX and RDX, and experimented with new cleaning
The method detection limit (MDL)\(^{(49)}\) for ten analytes, using the two SPE media and the GC/ECD method described, are presented in Table 6, and typically range between 3 and 20 ng L\(^{-1}\) for each analyte, regardless of medium considered.

The same authors also quantitated the explosives present in authentic groundwaters drawn from wells at several military installations using both membrane and cartridge SPE media and GC/ECD with HPLC confirmation. The concentrations of each analyte ranged over five orders of magnitude; in the specific case of TNT, the concentrations spanned 0.1 and 10 500 µg L\(^{-1}\). In all cases, virtually identical values were obtained using either extraction procedure and either method of determination.

### 3.3 Determination of Explosives in Seawater

The determination of explosives in seawater provides a challenging extension to those methods applicable to groundwater. For many years, the disposal of obsolete munitions was performed by merely dumping them in the ocean. In 1963, the United States Navy initiated a program in which obsolete Maritime Administration hulks were used for this purpose. These old Liberty ships were loaded with munitions and scuttled at sea.

One of the first procedures for determining explosives in this matrix involved the extraction of 100 mL seawater with benzene followed by evaporation of the resulting extract under reduced pressure. Quantitation was performed by GC/ECD, employing injection of 8–9 µL of concentrate onto a packed column. The limits of detection for TNT, RDX, and tetryl observed were estimated to be 2, 5, and 20 parts per trillion, respectively.\(^{(50)}\) This procedure was used to determine TNT, RDX, and tetryl in seawater, sediment, and ocean floor fauna samples taken from an explosives dumping area 85 miles west of Cape Flattery, WA, and from similar samples taken 172 miles south-southeast of Charleston, SC, at a nominal depth of 2500 meters. No explosive contaminants were found in any of the samples examined.\(^{(51)}\) Sediment samples were initially extracted with high-purity benzene. The solvent was subsequently evaporated completely, and the residues dissolved in 50 µL fresh benzene. Half of the concentrate was spotted along a ChromAr® 500 thin-layer chromatography sheet (glass fiber thin-layer chromatographic paper consisting of 70% Silicar TLC 7F containing a short wave, 254 nm, UV phosphor on 30% glass fiber), and developed with hexane–acetone (45:55 v/v) as eluent. The appropriate disks corresponding to the explosives were removed and re-eluted with benzene. Later, gas chromatographic analyses were performed on the final benzene concentrates. The limits of detection for TNT, RDX, and tetryl in tissues were determined by injecting 4.1 × 10\(^{-7}\) g TNT, 11 × 10\(^{-7}\) g RDX, and 17 × 10\(^{-7}\) g tetryl into a 51.4 g sea cucumber. After the usual subsequent workup and analysis, the figures of merit were estimated to be 47, 123, and 740 parts per trillion, respectively. The procedure for determining the detection limit was not given.

A very recent paper described the determination of explosives in seawater using solid-phase microextraction (SPME) fibers as the extraction medium, followed by quantitation using either HPLC or gas chromatography/ion-trap mass spectroscopy (GC/ITMS).\(^{(52)}\) The test matrix initially evaluated was synthetic ocean water, prepared by dissolving an appropriate quantity of “Instant Ocean” (a commercially available product) into high-purity water. This test matrix was then spiked with 50 ppb in each of TNT, RDX, 2-Am-DNT, 4-Am-DNT, and 2,4-DNT. Four SPME fibers, which exhibited widely differing polarities, were evaluated: poly(dimethylsiloxane) (PDMS, 100- and 65-µm thickness, nonpolar); polyacrylate (85 µm film thickness, polar); and Carbowax–divinylbenzene (65-µm thickness, polar). All determinations were performed with a Finnigan MAT GCQ GC/ITMS operated in the negative chemical ionization (CI) mode, with methane as the reagent gas.

The study demonstrated clearly that no one fiber was suitable for all of the analytes; however, the most suitable fiber for general use was Carbowax–divinylbenzene. Two critical figures of merit were calculated and reported, viz., the limit of detection (LOD) and the limit of quantitation (LOQ). Both of these quantities are defined in terms of X, the mean blank signal, and σ, the standard deviation of the blank signal. The LOD values, calculated as X + 3σ, were in the low (5–10) part-per-trillion range for all of the target NT analytes, but greater for the nitramines.

\(\text{MDL}\) for target analytes using GC/ECD a

\(^{(4)}\) 1-L water samples fortified to 10 ng L\(^{-1}\) preconcentrated to 4.0 mL acetonitrile using either cartridge or membrane SPE.

\(^{(5)}\) MDL greater than the spiked concentration and therefore not valid.

The LOD and LOQ \((X + 10\sigma)\) for RDX were 325 and 790 parts-per-trillion, respectively.

To test the utility of the developed method, both SPE and SPME were used for the analysis of several real oceanwater samples. Several pairs of samples, consisting of one-liter samples for SPE and 20-mL samples for SPME, were collected. The one-liter oceanwater samples were extracted through SDB-RPS SPE disks, which had been conditioned as described previously. The disks were washed with water, then ultrasonically extracted overnight with 4–5 mL acetonitrile. The recovered acetonitrile extract was then concentrated via nitrogen “blowdown” over a period of several hours to a final volume of 0.5 mL for HPLC and GC/ITMS analysis. The 20-milliliter oceanwater samples were separated into 5-milliliter aliquots for direct SPME sampling and GC/ITMS analysis.

The HPLC and GC/ITMS results using SPE generally agreed quite well for most of the samples. The SPE results, however, were often high compared to the SPE results. This behavior may be explained in several ways:

- The most probable explanation is that the SPE results may appear low due both to decreased extraction efficiency and losses in the lengthy analyte concentration/solvent evaporation process.
- The SPME results could appear high because SPME, with its fewer steps and sample transfers, may recover a greater portion of the sample.
- The accuracy of the SPE results may be biased high because the calibration curve was prepared using simulated oceanwater, while the samples contained real oceanwater. This is unlikely because “Instant Ocean” salt is designed to be an accurate surrogate matrix for seawater. The residual solvent “tail” in the gas chromatograms was significantly smaller when SPME, rather than disk SPE, was employed as the extraction method, as expected.

Caton and Barshick\(^{(53)}\) examined various ways to improve the qualitative and quantitative determination of TNT and its reduction products in SPE extracts of seawater using the Finnigan GCQ instrument described previously. The authors were able to detect 10 pg of TNT, 2,4-DNT, RDX, 4-Am-DNT, and 2-Am-DNT with a signal-to-noise ratio exceeding 6 using a standard 1 mL injection when the instrument was operated in the negative ion chemical ionization (NICI) mode.

Darrach et al.\(^{(54)}\) also investigated the use of SPME for ocean-related samples, including sediments which were contaminated with unexploded World War II-vintage undersea ordnance. This material was scattered in Halifax Harbor, Nova Scotia, Canada, after a minor fire in 1945 caused the detonation of a small nearby munitions bunker complex. The PDMS-divinylbenzene fiber exhibited the highest relative efficiency of the commercially available fibers for TNT extraction. After each extraction, the fiber was dried in a vacuum desiccator for at least 15 min. The analytes collected on the fiber were then desorbed and swept into a quadrupole mass spectrometer. Explosives detection was achieved using the reversal electron attachment detection (READ) method, which takes advantage of the NTs’ extremely large cross-section for attaching zero-energy electrons. The explosives detected in this work were TNT and DNT in sediments, at concentrations ranging from the low parts-per-billion to high parts-per-trillion (µg kg\(^{-1}\) to ng kg\(^{-1}\)).

Rodacy et al.\(^{(58)}\) described the determination of explosives in raw seawater or acetonitrile extracts (from solid-phase disk extractions) of seawater using the ion mobility spectrometer (IMS). Approximately 100 samples containing 10 ppb TNT or 20 ppb RDX (0.3 µL injections) can be analyzed at the rate of three per minute before excess water must be vented from the system. Scatter gradually increases from ±10% of the nominal value at the beginning of the series to ±25% at the end of the series. The scatter is presumed to be due to the increased concentration of water in the drift region. With direct injection of seawater samples, a large deposit of salt builds up in the injection liner. If this deposit remains, it sorbs some of the analyte, resulting in broad “stubby” peaks.

A better method of analyzing seawater samples is to deposit the sample aliquot onto a quartz sample tube or filter paper, followed by evaporation of the water. The residual explosive is then thermally desorbed in the standard manner. This method eliminates the problem of salt build-up in the injector, permitting samples up to several hundred microliters to be analyzed routinely. One obvious disadvantage, however, is that water evaporation can be relatively slow (several minutes), which decreases the sample throughput. To partially overcome this limitation, several samples may be prepared simultaneously. Alternatively, one can use a more volatile solvent, such as acetonitrile and acetone, and significantly decrease the amount of water required for the solvent to evaporate.

Rodacy et al.\(^{(58)}\) noted that the acetonitrile or acetonitrile extracts of seawater were frequently colored, from light to dark yellow, and even further to a deep green. For the most part, the compounds responsible for the color did not interfere with the analysis. On one occasion, the authors reported that the water surface was covered with what appeared to be millions of small (\(\frac{1}{4}\) inch and smaller diameter) jellyfish. On that one day, a chemical species in the extract, probably a jellyfish metabolite, was problematic.

The agreement between IMS and HPLC concentrations for explosives determined in the same extract was frequently excellent. At concentrations between 100 and 1000 parts per trillion (ppt), the IMS values averaged
42.2% less than the HPLC values determined using the standard Method 8330 (described in detail below). Between 1 and 100 parts per billion (ppb), the IMS values were 2.4% higher than the HPLC values. Between 100 and 800 ppb, the IMS data was 20.0% higher than the HPLC values. Overall, the IMS results agreed with the HPLC analysis within 7.3%, based on a data set representing nearly 200 samples. IMS values appeared to be biased low compared to those generated in the HPLC analyses, possibly due to nonlinearity of the calibration curve. The major problems involved with the IMS included severe sensitivity to vibration and the lack of robust structural construction, leading to frequent instrument failures.

### 3.4 Additional Procedures

The foregoing discussion has emphasized the determination of explosives in water using HPLC because the analytes are not degraded thermally, as they would typically be if gas chromatographic methods were employed. The thermal lability of explosives places a potentially severe limitation on the use of GC-based methods, which would offer far greater potential sensitivity and selectivity than their HPLC counterparts. To address this problem, Yion et al. evaluated a gas chromatograph equipped with a septum-programmable injector, which permitted cool on-column injections. The mass spectrometric detector was deployed in both its electron impact (EI) and CI modes (reagent gas isobutane). Two groups of explosives were evaluated: (A) TNT, tetryl, RDX, HMX, and PETN; and (B) 2,3-, 2,4-, 2,5-, 2,6-, and 3,4-DNT. The test samples were prepared by spiking water with a mixture of explosives at the desired concentration, then extracting them with dichloromethane. The extracts were taken to dryness; the residues were dissolved in methanol and injected into the gas chromatograph. The authors noted that the nitramines RDX and HMX did not degrade in the injection port. Tetryl, a chemically unstable analyte, formed N-methylpicramide in the ionization source prior to ionization as expected, but did not degrade further. The method enabled detection of 10 ppb TNT, RDX, HMX, and tetryl in water.

Feltes et al. quantitated explosives in aqueous samples using a variety of gas chromatographic detectors, including mass spectrometric detectors in three different modes, viz. EI: positive-ion chemical ionization (PICl); NICI; ECD; and the chemiluminescent nitrogen detector (CLND), also known as the Thermal Energy Analyzer (TEA). SPEs of fortified one-liter water samples were performed with cartridges packed with resins (XAD-2, XAD-4, XAD-8) or silica-based SPE media (octadecyl, phenyl, cyano). The explosive analytes were eluted with a small volume of dichloromethane, which was later dried over anhydrous sodium sulfate and reduced in volume to about 1 mL in a rotary evaporator after exchange of the solvent to methanol.

The authors noted that while nitroaromatics can be determined successfully by ECD as a result of their high electron affinity, the response for nitroaromatics depends strongly on the individual compound. On the other hand, the CLND response is more similar for all the compounds because the nitrogen content of each analyte does not vary as sharply as the electron affinity. For example, the CLND response ratio of 3,4-DNT to 2-NT is 3.4, while the corresponding ECD response ratio is 61. The CLND exhibits excellent selectivity towards nitrogen-containing analytes, and is therefore better suited for the determination of explosives in complex environmental samples than the ECD, which is less selective. On the other hand, the ECD is approximately three orders of magnitude more sensitive than the CLND. The authors compare and contrast the merits of the various detectors as follows:

As a result of their high electron affinities, nitroaromatic compounds can be determined with high sensitivity by GC using ECD. If, however, highly polluted surface water is to be investigated, ECD is not sufficiently selective for an unambiguous compound assignment. In contrast, a chemiluminescence detector is more sensitive and selective than EI, but gives fewer structure-specific fragments. [Reproduced by permission of Elsevier Science Publishers B.V. from J. Feltes, K. Levsen, D. Volmer, M. Spikermann, *J. Chromatogr.*, 518, 39 © 1990.]

One highly successful, but seldom-used, approach for improving the sensitivity of HPLC-based quantitations of explosives is to derivatize the analytes in a post-column reactor, such as that described in Engelhart et al. Initially, the explosives were photolyzed by elution through a photo reactor consisting of 20 meters of crocheted Tefzel™ capillary tubing coiled around a low-pressure mercury lamp (254 nm). In the second step, the nitrite ion so generated is reacted with colorimetric reagents, such as sulfanilamide and [naphthyl-(1)]-ethylene diammonium chloride, to form an azo dye whose absorbance can be monitored at 540 nm (via the Griess reaction, discussed in detail elsewhere in this chapter). Using this approach and nominal 5 to 10 µL injections, it was possible to detect selectively 25–50 ppb nitramines and 30–100 ppb of nitrate esters, even in complex mixtures. The detection limit for esters and nitramines was approximately 100 pg using the derivatization, compared to approximately...
100 µg unreacted. Only for the nitroaromatic explosives is a UV detection system twice as sensitive as the detection system described here.

4 DETERMINATION OF EXPLOSIVES IN SOIL SAMPLES

4.1 Extraction Techniques for Explosives Residues in Soil: Initial Considerations

Many of the analytical procedures employed for the determination of explosives in aqueous samples may also be used for their analysis in soils. The most important difference between the overall methods is, of course, the exact procedure(s) employed to extract the analytes from the matrix. The explosives range in polarity from the moderately polar DNT and TNT to the highly polar HMX and RDX; hence, the choice of extraction solvent becomes an important variable. In addition, there are a variety of generally accepted procedures available for extracting solid samples, including Soxhlet extractors, ultrasonic baths, mechanical wrist-action shakers, and homogenizer–sonicators. Two very recent additions to this list are supercritical fluid extraction (SFE) and accelerated solvent extraction (ASE).

Jenkins and Grant(60) performed an extensive optimization study for the extraction of explosives in soil. The test matrix, taken from the Iowa Army Ammunition Plant, was the surface of an old ordnance burning area that had not been used for several years prior to sampling. The extraction behavior of two soils and four analytes, viz., TNB, RDX, HMX, and TNT, were evaluated during this study. The authors noted that the solubilities of RDX and HMX were over twenty times higher in acetonitrile than in methanol; hence, acetonitrile was the preferred extraction solvent. The performance of acetonitrile was equivalent to that of methanol for TNT and TNB. Both solvents were suitable for the HPLC determinations which would be employed subsequently. The extraction techniques evaluated were Soxhlet, ultrasonic bath, mechanical wrist-action shaker, and homogenizer–sonicator. Both the Soxhlet extractor and ultrasonic bath recovered more than the homogenizer or shaker. The ultrasonic bath and shaker offered additional advantages to Soxhlet and homogenizer–sonicator in that several samples could be processed simultaneously.

The chromatographic separations of the analytes were performed using the HPLC methods described previously for groundwater samples. The explosives were eluted from the “primary” column (Supelco LC-8, 250 × 4.6 mm, 5 µm particle size) using a water–methanol–acetonitrile eluent (50:38:12 v/v/v, 1.5 mL min⁻¹). The “confirmation” procedures employed either a Supelco LC-CN or LC-18 column (both 250 × 4.6 mm) using 50:50 v/v water–methanol eluent. LC-CN, which is frequently used as a “normal” phase column, was particularly effective for confirmation because the elution order was almost completely inverted from that observed for LC-8 and LC-18, which are both strictly “reversed” phase columns. Since few commercial laboratories are equipped to use either the electrochemical detector or TEA with LC (liquid chromatography), and the intent is to develop a method for general use, the authors concentrated on UV detection. A wavelength of 254 nm was chosen because a variety of manufacturers offer a fixed wavelength detector based on the mercury lamp emission line at 254 nm. All analytes of interest absorbed either strongly (nitroaromatics) or modestly (nitramines) at this wavelength, while potential interferences such as chlorinated organic compounds do not.

Overall, the sonic bath method is recommended because it is inexpensive and can be used to process a number of samples simultaneously and unattended. The gentle heating that occurs with the sonic bath (∼39 °C) also seemed desirable to increase the rate at which equilibrium is attained. The sonic bath does not suffer from the problem experienced with the Soxhlet device of co-extracting significant amounts of interfering substances that have a low solvent–soil partition coefficient. It is also worth noting that the Soxhlet extraction of thermally labile analytes such as tetryl frequently presents unexpected difficulties. On the other hand, there were some disadvantages and/or precautions to be noted in conjunction with sonic agitation. Analyte extraction efficiency may depend on the vigor of agitation, which depends on many variables for sonic devices. It had been observed that the extent of particle disruption varies inversely with solid/solution ratio; consequently this ratio should be constant in comparison analyses. Solvent variables such as viscosity, vapor pressure, and dissolved air concentration affect acoustic impedance. Not surprisingly, temperature increases allow cavitation bubbles to collapse with less force; consequently, the increased solubility may be offset by reduced agitation. However, as long as conditions are held constant, the sonic bath represents an excellent way to perform such extractions.

4.2 Experimental Considerations and Statistical Validation of the Proposed Standard Method

The procedure sketched above was subjected to a rigorous statistically constructed collaborative study involving eight independent laboratories. An open-literature paper describing this study(64) thoroughly explained many of the critical experimental details. For example, air-drying of the soil samples away from direct sunlight for at least 24 hours prior to extraction minimized
Prior to analysis by LC, the soil extracts had to be filtered to protect expensive reverse-phase columns. Because of the long period of sonication required for maximum analyte recovery, the soil aggregates were dispersed into very fine particles with long settling times. These fine particles made filtration of the extracts extremely difficult, even after the extracts were centrifuged at 5000 rpm for extended periods of time. Rupturing of the membranes sometimes occurred due to the excessive pressure required. For this reason, additional steps had to be introduced to enable facile filtration of the acetonitrile extracts. Adding aqueous calcium chloride solution (optimized concentration 5 g calcium chloride L$^{-1}$) produced flocculation of the fine particles and rapid settling for most soils. After a 15-min settling time, the clarified solutions were readily filtered through 0.5 μm filters.

Stock standards of explosives dissolved in acetonitrile can be safely used for periods up to one year if they are stored in glass, at 4 °C, in the dark, and with precautions to minimize solvent evaporation. Working standards can be prepared and used over a 28-day period if refrigerated and kept in the dark when not in use. In general, extracts can be held for up to two months without large adverse effect.

The HPLC methods employed the columns and methodology described previously. The target analytes were all resolved when eluted from a Supelco LC-18 column (25 cm × 4.6 mm i.d., 5 μm particles) with methanol–water (1:1 v/v). These explosives were also eluted and resolved using the same eluent from the “confirmation” column, which was a Supelco LC-CN (25 cm × 4.6 mm, 5 μm particles), but in a nearly inverted order. UV detection at 254 nm was employed, as discussed previously. Weisberg and Ellickson$^{(65)}$ further recommended a complete solvent change to methanol with a 5-min hold to flush the column, followed by a gradual return to the initial program conditions over a 5-min period. This practice elutes nonpolar nontarget analytes that will otherwise elute in subsequent samples and interfere with the usual determination method. The authors observed that the benefits of greater baseline stability outweighed the longer analysis turnaround time.

Overall, the method described above was sufficiently robust and reliable to be approved for both “Official First Action” and “Final Action”, first by the AOAC, then by the USEPA (Method 8330, “Determination of Concentration of Nitroaromatics and Nitramines by High-performance Liquid Chromatography”). The MDL$^{(66)}$ and CRL values were calculated for thirteen target compounds, as shown in Table 7. MDL values ranged between 0.03 μg g$^{-1}$ soil for 2,4-DNT and 2-Am-DNT, to 1.27 μg g$^{-1}$ for HMX; however, HMX was the only species where the MDL exceeded 1 μg g$^{-1}$. Recoveries ranged between 80% (for HMX) to 119% (for TNB).

4.3 Performance of the Standard United States Environmental Protection Agency Method 8330

Soil samples obtained from two independent EOD sites were analyzed by staff members of the Cold Regions Research and Engineering Laboratory (CRREL) and Missouri River Division Laboratory (MRD). At both sites, 2,4-DNT was detected in all samples with detectable analytes. The 2,4-DNT was present at much higher concentrations than TNT, the reverse of what is found at other types of sites. The source of this contamination was probably the improper demolition of excess propellant (i.e. it was detonated, not burned). In fact, whole propellant grains were found scattered about each EOD site.

GC/MS analysis of acetonitrile extracts of soil samples and propellant grains confirmed the presence of diphenylamine and dibutylphthalate, which, along with nitrocellulose (NC) and 2,4-DNT, are the ingredients of M1 propellant.\(^4\) Most analytes could be confirmed using the cyano (LC-CN) confirmation column eluted with 1.5 mL min\(^{-1} \) 1:1 methanol–water, as specified in Method 8330. HMX and RDX, which elute several minutes before TNT on the analytical column (LC-18), elute after TNT on the confirmation separation. This dramatic shift in retention order makes the confirmation of nitramines certain. However, confirmation of DNT is difficult in many cases. The isomers of DNT elute close to TNT on the confirmation separation, and since they are often present at much lower concentrations than TNT, their confirmation may be ambiguous. However, some improvement in the resolution of 2,4-DNT and TNT can be achieved using a slower flow rate (1.2 mL min\(^{-1} \)) and a weaker eluent (35 : 65 methanol–water). Additionally, this flow rate and eluent greatly improve the separation of 2-Am-DNT and TNT.

Another problem associated with the confirmatory separation for some samples is the presence of many more peaks in the confirmation chromatogram than in the

analytical chromatogram. The cyano function on the LC-CN “confirmation” column is less retentive for aromatic compounds than the hydrocarbon-based phases of the LC-18 or LC-8 “primary” analytical columns. Because the confirmation column is less retentive, it is more prone to interference from nontarget analytes that have long retention times on the LC-18.

The concentration ranges observed in this study for various explosives and related products in soils and water ranged from “nondetectable” to thousands of parts-per-million in soil or water, as shown in Table 8.

4.4 Additional Procedures

Several new approaches to the extraction and quantitation of explosives in soil have given the analytical chemist more choices for determining these species both rapidly and reliably. For example, ASE™ employs both elevated temperature and pressure to extract a solid sample in a sealed vessel rapidly. A manufacturer’s application note describes the rapid extraction (14 min) of small soil samples using either acetone or methanol (17–50 mL sample⁻¹). This approach was tested with clean soil spiked with explosives, authentic contaminated soils from Germany, and heavily contaminated wet soil. For the latter, 2.5 g soil were mixed with 0.8 g diatomaceous earth prior to extraction. In all cases, the recoveries from the ASE™ were greater than those with sonication. Parallel results obtained using Soxhlet extraction were not reported. Extractions from wet heavily contaminated soils were reproducible (6% RSD at 3500 mg TNT kg⁻¹).

Griest et al. described the separation of explosives using packed-column supercritical fluid chromatography (SFC). The eluent employed was SFC-grade carbon dioxide using the SB-Cyanopropyl-25 capillary column (5.0 m x 0.05 mm i.d.). HMX was finally eluted as a clean sharp peak with supercritical fluid grade carbon dioxide using the SB-Cyanopropyl-25 capillary column (5.0 m x 0.05 mm i.d.); however, resolution of the earlier-eluting explosives was sacrificed compared to that observed in Griest et al. Miyares also compared the instrumentation and ease of method development between SFC and HPLC, and noted the following:

- SFC columns are smaller and more flexible than GC columns, and are much harder to install than HPLC columns. HPLC columns may be installed or removed in less than one minute, compared to up to 15 minutes for SFC columns.
- Method development involving reversed-phase HPLC columns is fairly straightforward because retention times are strongly correlated to octanol–water partition coefficients. It becomes reasonably easy for an experienced operator to choose the column phase, mobile phase, and gradient (if required). In SFC, the partitioning of analytes between the mobile and stationary phases is part of the partition mechanism for separation, but it may also include specific effects from density, temperature, linear velocity, and volatility of analytes. The temperature, density, and pressure of supercritical fluids are interrelated in such a way that for a given density, there are many temperature and pressure combinations. Consequently, considerably more trial-and-error is required for SFC method development than for HPLC method development.
- The standard HPLC method employs simple isocratic elution, which may be executed using even very unsophisticated pumping systems. In contrast, the SFC separation reported in Miyares required an intricate combination of temperature and density ramps which demanded a highly sophisticated pumping system.

Taken together, Miyares concluded that for routine environmental monitoring and site characterization required by the military, SFC offered no substantial advantages over the standard HPLC/UV methods.

Rodacy et al. discussed the application of IMS both to aqueous samples, as discussed earlier, and soils. Explosives are desorbed thermally from soil samples prior to introduction into the IMS. Each explosive examined to date, including TNT, RDX, PETN, ethylene glycol dinitrate (EGDN), NG, HMX, and DNT have unique and repeatable delay times for any given temperature up to the point where sample decomposition occurs. The type of soil being analyzed does not affect the relative delay times because explosives desorbed from soils containing high sand content, high clay content, high humic matter, and pure quartz surfaces show the same relative delays. However, if one compares the length of time it takes for an explosive to be desorbed from, say, a sandy soil and a soil with high humic content, a slight difference in desorption times can be noted. The differences, however, are minor
5 DETERMINATION OF EXPLOSIVES USING FIELD SCREENING PROCEDURES

5.1 Introduction and Motivation

The preceding discussions all tacitly assumed that the determination of explosives in either aqueous or soil samples would be performed (a) using standard well-validated methods (b) using highly instrumented analytical methods (c) in a well-equipped laboratory (d) in a timely manner. Such scenarios frequently are not helpful for routine site clean-up operations. “Traditional” analytical laboratories are rarely available at a clean-up site. Further, reliable analytical data needs to be available immediately so that remediation personnel may make correct and timely decisions. Lengthy delays imply that expensive excavation equipment and skilled operators must remain idle for indefinite periods of time. Crockett et al. described additional complications and considerations as follows:

- Explosives may be detected easily at low concentrations if they are artificially spiked onto a soil sample. The analyte does not have sufficient time to diffuse into the tiny pores on the surface, and is therefore removed easily.
- Explosives may be detected at concentrations exceeding hundreds of ppm (i.e., >0.01%) in authentic contaminated soil, but not at lower levels.
- The sensitivity of the IMS instrument is critically dependent upon the design of the desorption furnace (short vs long heated zones). The transfer line must be heated to avoid any possible cold spots which would promote analyte condensation prior to introduction into the ion source.
- TNT is detected as TNT, rather than as a degradation product.

Jenkins and Walsh extended previously reported work concerning the application of GC/ECD in aqueous samples to include soils. Use of this approach permitted detection limits of about 1 µg kg⁻¹ for the important signature chemicals, without additional pre-concentration. This method employs short (6 m) Mega-bore (0.53 mm i.d.) fused silica columns with deactivated injector liners and linear velocities of about 100 cm s⁻¹. The authors resolved 20 important nitroaromatic, nitramine, and aminonitroaromatic signature chemicals within a 15-minute analysis time using a 6-m HP-5 column. This method has been given preliminary approval by the USEPA as SW-846 Method 8095.

Yinon et al. described the application of thermal pyrolysis/GC/MS for several explosives, including RDX, HMX, tetryl, monoaminotrinitrobenzene (MATB), diaminotrinitrobenzene (DATB), and triaminotrinitrobenzene (TATB). The final pyrolysis temperature was 400–1000°C, held for 2 seconds. The nitramines RDX and HMX showed similar mass spectra upon pyrolysis, both of which were very different from those of the three nitroaromatics.
Reliance on laboratory analyses only for site characterization may result in a large percentage of samples (up to 80%, depending upon the site) with nondetectable levels. The remaining samples may indicate concentrations within a range of four orders of magnitude. Analyzing a small number of samples at an off-site laboratory may result in inadequate site characterization for estimating soil quantities for remediation and may miss potentially reactive material. ... Laboratory analytical costs vary depending on required turnaround time. Typical costs for USEPA Method 8330 range from $250 to $350 per sample for 30-day turnaround, $500 to $600 for 7-day turnaround, and approximately $1000 per sample for 3-day turnaround, if it is available. [Reproduced by permission of the Cold Regions Research and Engineering Laboratory from A.B. Crockett, T.F. Jenkins, H.D. Craig, W.E. Sisk, Overview of On-Site Analytical Methods for Explosives in Soil, Special Report 98-4, 3, 1988.]

Taken together, there is an urgent demand for analytical procedures which are:
- well-documented and validated;
- fieldable at clean-up sites;
- easily operated by nonchemical professionals;
- rapid;
- capable of producing valid analytical data quickly;
- inexpensive.

5.2 Description and Evaluation of Typical Colorimetric Field Screening Procedures

Many of the existing and successful analytical field test kits for explosives in environmental samples are based upon two well-documented chemical reactions. As early as 1891, Janowsky(75) observed that colored reaction products were observed when polynitroaromatic compounds reacted with alkali such as potassium hydroxide in the presence of acetone. Meisenheimer(76) and Jackson and Earle(77) independently proposed a final end product with a quinoidal structure to explain this phenomenon. In general, Jackson–Meisenheimer anions for nitroaromatics are blue to purple in color and those from trinitroaromatics are red.(78) The formation of Jackson–Meisenheimer anions has historically been the basis of a reliable field test for nitroaromatics. The reactions are summarized in Scheme 1.

Colorimetric chemical methods have also been developed for RDX and the nitramines for forensic applications.(79) These procedures generally rely on sequential reactions where zinc metal converts RDX, for example, to nitrous acid (Franchimont reaction). The resulting nitrous acid is used to nitrosate an aniline derivative such as sulfanilic acid; the resulting diazo cation is then coupled to a naphthylamine to form a highly colored azo dye (Griess(80) reaction). This reaction sequence is summarized in Scheme 2. Several pairs of reagents may be used to produce azo dyes. A reagent containing procaine and N,N-dimethylamylamine was initially used for the procedure described in Jenkins and Walsh.(81) This choice was based on the work of Wyant, who tested several reagents and found this combination best in terms of detection capability and shelf life.(82) However, this liquid reagent is light-sensitive, and therefore cumbersome to handle in the field. In addition, there was some concern about the possible cancer risk associated with N,N-dimethylamylamine. Further work demonstrated that a Hach NitrilVer 3 “powder pillow”, which is specifically designed for the determination of nitrite in the field, and distilled water, can be substituted for the liquid Griess reagent. The powder pillow contains sodium sulfamate, 4,5-dihydroxy-2,7-naphthalene-disulfonic acid disodium sulfate, potassium phosphate monobasic, potassium pyrosulfate, and trans-1,2-diaminocyclohexane tetra-acetic
Acetone and absorb strongly at 460 nm. Yellowish humic materials that are also extracted into wavelength was selected to reduce interferences from and the nitramines. While absorbance of the Janowsky (for TNT and nitroaromatics) and 507 nm (for RDX be used to quantitate the products so formed at 540 nm be reacted with a strong base and sodium sulfite. If only TNT is present, a reddish blue-purple complex is produced. If only DNT is present, a reddish pink Griess reaction product is indicative of the presence distilled water, as described above. The development of a native nitrate or nitrate, is acidified and reacted with a red azo dye compound.

Jenkins and Walsh described colorimetric field screening procedures (the “CRREL Methods”) for explosives. Approximately 20 g wet soil is shaken with 100 mL acetone, and the extract filtered with a disposable syringe filter. The first test is designed to detect nitroaromatics. Portions of the extract are reacted with a strong acid trisodium salt. Abramovich-Bar et al. described an additional set of workable Griess reactants. Here, a diazonium salt is formed from sulfanilamide and nitrite in the presence of 10% phosphoric acid. This product, in turn, reacted with n-naphthylethenediamine to produce a red azo dye compound.

Jenkins and Walsh described colorimetric field screening procedures (the “CRREL Methods”) for explosives. Approximately 20 g wet soil is shaken with 100 mL acetone, and the extract filtered with a disposable syringe filter. The first test is designed to detect nitroaromatics. Portions of the extract are reacted with a strong base and sodium sulfite. If only TNT is present, a reddish blue-purple complex is produced. If only DNT is present, a reddish pink Griess reaction product is indicative of the presence of RDX or one of several other military explosives which are potential interferents (HMX, NG, PETN, or nitrocellulose (NC)). A battery-operated spectrophotometer may be used to quantitate the products so formed at 540 nm (for TNT and nitroaromatics) and 507 nm (for RDX and the nitramines). While absorbance of the Janowsky product is greater at 460 nm than at 540 nm, the latter wavelength was selected to reduce interferences from yellowish humic materials that are also extracted into acetone and absorb strongly at 460 nm. The detection limit was 1 µg g⁻¹ for TNT and RDX, with linear range extending to 50 µg g⁻¹ for TNT and 20 µg g⁻¹ for RDX.

Medary reported a related screening procedure for TNT in which methanol, not acetone, was the extraction solvent. TNT was estimated for the absorbance of the colored Meisenheimer anion produced at 516 nm, and 10 minutes) were useful for soils with a “heavy” clay content.

The color-forming reactions used for these field screening methods are not specific for TNT, 2,4-DNT, and RDX. Other polynitroaromatics such as 1,3-DNB and 1,3,5-TNB and polynitrophenols such as picric acid (PA) also give colored anions when reacted with strong base. During site clean-up activities, however, the ability to detect these other compounds, as well as TNT and 2,4-DNT, would be quite useful. Similarly, the same azo dye produced from the RDX test is also produced when other nitramines such as HMX and tetryl or nitrate esters such as NG, PETN and NC are treated under similar conditions. Heavy metal cations such as copper were found to interfere with the 2,4-DNT determinations. These cations could form complexes with either the unreacted DNT or the Janowsky complexes.

Absorbance varied little for the TNT and RDX solutions over the range of moisture contents (10–75%) expected for the large majority of surface soils from potentially contaminated sites. However, the absorbance for the 2,4-DNT standard significantly declined as the water content exceeded 10%. Based on this variability, determinations for 2,4-DNT will be semi-quantitative, while the corresponding procedures for TNT and RDX may be used quantitatively.

The extraction procedure described in Jenkins and Walsh was field-tested extensively with authentic contaminated soil samples. The concentrations obtained in the field for TNT, RDX, and 2,4-DNT were compared with those using USEPA Method 8330, which was described previously. In all cases, there was excellent agreement obtained between the concentrations obtained using the two procedures; the typical recovery using the field procedure exceeded 90%. These data are summarized in Table 9. The success of the colorimetric method for TNT led to its adoption as a standard analytical method, entitled USEPA Method 8515, “Colorimetric Screening Method for Trinitrotoluene (TNT) in Soil”. The RDX method has also undergone standardization as SW-846 draft method 8510.

5.3 Description of Antibody-based Field Test Kits

Recent alternatives to the classical colorimetric assays for explosives, such as those described above, are field tests employing enzyme-linked immunosorbent assays (ELISA). One such assay for TNT involves several steps. In step 1, the plate is precoated with a TNT-protein conjugate that adheres to the well surface. In step 2, competitive inhibition occurs when samples containing TNT are incubated with mouse anti-TNT antibodies. The antibodies can either bind to the free TNT in the

...samples or to the TNT bound to the surface of the well. After an equilibrium is reached, the plate is washed and the antibodies bound to the free TNT are washed away, leaving the antibody bound to the immobilized conjugate. The greater the concentration of TNT in the sample, the less monoclonal antibody is available to the immobilized TNT conjugate. Therefore, the amount of antibody bound to the well is inversely proportional to the TNT concentration present in the sample. In step 3, the plate is incubated with goat anti-mouse (µ-chain specific)-alkaline phosphatase conjugate which bonds only to the surface-bound mouse monoclonal anti-TNT antibodies. The plate is washed again. In step 4 the enzyme substrate is added. The surface-bound enzyme–antibody conjugate converts the colorless substrate to a yellow product. The color is directly proportional to the amount of TNT monoclonal antibody bound in each well, and, therefore, is inversely proportional to the amount of TNT in the sample. Mouse monoclonal anti-TNT antibody for TNT is specific for TNT and shows no cross-reactivity with those explosives or interferent tested in this study. The assay was capable of detecting as little as 50 pg TNT.

Musk, as well as a number of other chemicals, are known to present potential interferences with chemical or instrumental means of explosive detection. For example, synthetic nitro musks are similar in chemical structure to TNT and are common fragrance additives in toiletries. To determine the effects on the assay, 100 µL of 2 undiluted musk perfumes – an extreme quantity – were added directly to the microtiter plates in triplicate. In these cases, some inhibition of color development was observed. This may be due to partial stripping of the coating antigen from the plate or binding to the monoclonal anti-TNT antibody.

Westinghouse’s Law Enforcement Products Division has developed an antibody-based method for PETN using a latex-bead agglutination technology. Agglutination reactions are widely used throughout the biochemical community for the detection of small quantities of...
proteins and drugs in physiological fluids. The time required to complete a PETN assay was reduced to 30 seconds. The sample collection device and assay are being incorporated into a disposable item which is analyzed using a reusable hand-held spectrophotometer. In step 1 of the assay, agglutinated latex particles form when the latex particles (<1 µm particles) which have covalently bound to their surface the analyte of interest, are mixed with the specific antibody. Because of the multiple binding sites on both the latex particles and the antibody, a crosslinking or polymerization of many particles occurs. In the presence of the analyte of interest, this agglutination is inhibited. This agglutination reaction can be monitored both visually and electronically in about 30 seconds. PETN antibodies from one particular rabbit showed detection as low as 30 parts per trillion using an ELISA assay similar to the TNT assay. Recent preliminary results of the agglutination assay have demonstrated a detection limit of 25 ng of PETN.

Bart et al. described a continuous-flow immunosensor (CFI) which would be capable of fulfilling the mission of an explosives detector for both environmental analysis and bomb detection. The CFI is a semi-automated system in which the analyte-containing medium (generally an aqueous sample which is spiked with a concentrated solution of buffer, organic co-solvent, and a surfactant) is pumped through a column containing antibodies immobilized on beads. These antibodies are saturated with a fluorescent analog of the analyte before the analysis begins. As the analyte passes through the antibody matrix, some of the analyte binds to the antibody, displacing the labeled analog. The effluent from the column is thus a mixture of analyte which did not bind to the antibodies and dye-labeled antigen which was displaced by the analyte; the fluorescent analog is then detected in a fluorometer located downstream from the column. The amount of dye-labeled antigen displaced is directly related to the amount of analyte in the sample. A prototype system was assembled and evaluated for the evaluation of RDX in aqueous samples over the range 15–1200 ng RDX mL⁻¹. The lowest detectable limit was 20 ng RDX mL⁻¹. The cross-reactivity of other explosives with the anti-RDX antibody was modest for HMX (15% response vs RDX), and minimal for TNT and its derivatives (typically <1%). This behavior was expected because of the structural similarities of RDX and HMX, and dissimilarities of RDX and TNT. When both the CFI and standard HPLC methods were used to analyze several groundwater samples for RDX, the agreement between the two methods was excellent. Kusterbeck and Charles described the extensive field demonstration of a similar device, the FAST 2000, for the determination of TNT at two Department of Defense Superfund cleanup sites. The procedure was cost-effective and capable of screening a number of samples in a short period of time at a project cost of approximately $3–$10/sample, compared to $250–$1000/sample using the standard HPLC method.

5.4 Evaluation of Commercially Available Field Screening Kits

The frequency of occurrence of specific explosives in soils was assessed using analytical data on soils collected from 44 army ammunition plants, arsenals, and depots, and two EOD sites. Of the 1,155 samples, a total of 319 samples (28%) contained detectable levels of explosives. TNT was detected in 66% of the samples and 80% of the samples if the two EOD sites are excluded. Overall, TNT or RDX or both were detected in 82% of the samples containing explosive residues, and 94% if the ordnance sites are excluded. Thus, by screening for TNT and RDX at these facilities, 94% of the contaminated areas could be identified (80% if only TNT was determined). This demonstrates the feasibility of screening for one or two compounds. Screening for all of the explosives listed in USEPA Method 8330 was not necessary to evaluate the degree of contamination in a particular site. For that reason, several manufacturers now offer commercially available test kits which focus on the determination of TNT and RDX. These kits have been evaluated extensively by many independent authors, with their performance summarized in the following general comments:

- A USEPA study compared the CRREL, EnSys (colorimetric), D Tech, Quantix, and Ohmicron methods for TNT. Overall, no single method significantly out-performed other methods, and the accuracies for all the field screening methods were comparable.
- Myers et al. compared the EnSys colorimetric test to a commercial enzyme immunoassay (EIA) procedure that utilizes an immunofiltration approach (D Tech) using 99 soil samples obtained from the NSWC. The results from both methods were compared with analyses conducted using the standard reversed-phase high-performance liquid chromatography (RPHPLC) laboratory procedure (SW-846 Method 8330). Quantitative agreement between the field screening results and the RPHPLC results was somewhat better for the colorimetric method; however, a portion of this advantage may be due to larger sample sizes utilized in the EnSys protocol, which results in reduced sampling error.
Haas and Simmons\(^{(92)}\) evaluated immunoassay kits for TNT (EM Science/D Tech, EnSys/EnviroGard Tube and Plate, Idetek/Quantix, and Ohmicron/RaPID Assay.) They concluded that for semi-quantitative screening, all kits have the potential to accurately screen soil samples for contamination at risk-based levels. The correlation between the immunoassay kits and HPLC was generally good above the 1 ppm level.

A study conducted by the USEPA Region 10\(^{(93)}\) and reported in Jenkins et al.\(^{(1)}\) compared two versions of the colorimetric test (CRREL\(^{(81)}\) and the EnSys commercial version) and two commercial immunoassay methods (D Tech and Quantix) during Phase 1 of the explosives washout lagoon soil remediation project at the Umatilla Army Depot. Samples were also analyzed using RPHPLC Method 8330; these results served as the basis for comparison. Overall, the CRREL colorimetric method was judged the least expensive for large sampling efforts and the most accurate for concentrations above 30 µg g\(^{-1}\), while the D Tech EIA procedure was judged the most accurate below 30 µg g\(^{-1}\). The Quantix method, which utilizes an EIA approach in the plate format, was judged the most efficient method for large numbers of samples. Overall, this study confirmed the value of the use of field screening for explosives-contaminated sites.

A major field demonstration and evaluation of on-site analytical methods was performed during full-scale remediation at the Umatilla Chemical Depot (Hermiston, OR) and US Naval Submarine Base (Bangor, WA) Superfund sites. An additional evaluation involved pilot scale composting at the NSWC (Crane, IN) RCRA Corrective Action site.\(^{(94)}\) Compost samples were analyzed by each of the on-site methods and results compared to standard laboratory analyses employing HPLC. The on-site methods evaluated included EnSys TNT and RDX colorimetric methods (USEPA SW-846 Methods 8515 and 8510) with and without an organic matrix cleanup step, and D Tech TNT and RDX immunoassay methods (USEPA SW-846 Methods 4050 and 4051). This study indicated that both colorimetric and immunoassay methods may be used for determination of explosives concentrations in compost residues during bioremediation treatment.

5.5 Field Test Procedures for Picric Acid and Ammonium Picrate

Ammonium picrate (AP; Explosive D; Yellow D) was used in armor-piercing shells, bombs, and rocket warheads by the US military from the turn of the century until after World War II. Although it is no longer manufactured, AP represents 8% of the demilitarization inventory. Picric acid (PA) was used in grenades and mine fillings. Unlike many of the other high explosives that are no longer manufactured and present environmental clean-up problems unique to the military, PA is a common industrial chemical, used widely for metal etching and as a feedstock in many processes in the dye, leather, and glass industries.\(^{(95)}\)

Thorne and Jenkins\(^{(95)}\) described the optimization of a field analytical method for AP/PA in considerable detail, with the final procedure sketched as follows: soils are extracted with acetone in a manner similar to the colorimetric screening methods for TNT and RDX. A 30-mL filtered aliquot is mixed with 30 mL of deionized water and passed through a 3-mL SPE-Alumina-A (Supelco) cartridge. Picrate ion is retained on the alumina. Interferences are removed by passing a 3-mL aliquot of methanol through the cartridge, followed by a 3-mL aliquot of acetone. Picrate is converted to PA with a solution of 10 mL acetone containing four drops of sulfuric acid and eluted from the cartridge. The solution is then diluted with 5 mL of deionized water and 15 mL of acetone. A change from the colorless (PA) to yellow (picrate) is indicative of the presence of PA/PA in the soil at a concentration above 3 µg g\(^{-1}\). The picrate concentration can be estimated from the absorbance of the solution at 400 nm with a MDL of 1.3 µg g\(^{-1}\). In the same study, concentrations of picrate were measured in 49 contaminated soil samples using both the field method described and RPHPLC. The results obtained exhibited an excellent correlation over three orders of magnitude. The field method did not produce false positives.

5.6 Field Screening Procedures for Explosives in Soils using Ion Mobility Spectrometry

IMS was evaluated as a potential field screening procedure for explosives in soil.\(^{(96)}\) The US Army provided a large number of soil samples that had been collected from three locations at each of three explosive contaminated installations, dried, ground, homogenized, and previously analyzed in duplicate using Method 8330. Duplicate two-gram aliquots of these samples were extracted with 10 mL of acetone by shaking for three minutes. After solids had been allowed to settle, the quantities of “typical” explosives were determined using IMS. For field application, the extraction procedure should be changed to 20 g moist soil, 100 mL acetone. The chief limitation of the IMS method was the initial cost of instrumentation (~$50 K).
6 TRANSFORMATION AND METABOLISM OF EXPLOSIVES IN THE ENVIRONMENT

6.1 Expected Reaction Pathways

The presence of species such as TNB and the various isomers of poly-amino poly-NT suggest that TNT residues in soil may be transformed by a variety of photochemical and/or microbiological processes. While the transformation pathways of some explosives have been studied in cell cultures, composting systems, and water, little research has been conducted to define what by-products are present in explosives-contaminated soil. Griest et al.\(^\text{[97]}\) have reported the aquatic toxicity of TNT and its metabolites by using the *Ceriodaphnia dubia* assay. The same source discussed the mutagenic and genetic activity of the same compounds using the Ames test, Chinese Hamster Ovary (CHO) assay, and the Sister Chromatid Exchange (SCE) assay. Potential transformation products of TNT are numerous. Major et al.\(^\text{[8]}\) outlined the following two major and one minor transformation pathways:

- An *oxidation* pathway, in which the methyl group of TNT is oxidized stepwise to the corresponding alcohol, aldehyde, and acid. The latter is ultimately decarboxylated to form 2,4,6-TNB.

- A *reductive* pathway, in which either the 2- or 4-nitro group of TNT is reduced stepwise to the corresponding hydroxylamine and amine. The reduction of the remaining nitro groups would proceed similarly, ultimately forming a 2,4,6-triaminotoluene (TAT) end product. Many bacteria and fungi are capable of performing this reduction.\(^\text{[39]}\) The reduction only proceeds to the monoamine stage under aerobic conditions, and may occur abiotically.\(^\text{[98]}\) If the medium considered is composted soil, which contains a significant quantity of humic organics, a significant fraction of the reduced TNT products will become covalently bound to the matrix.\(^\text{[99]}\)

- A *condensation* pathway, in which monoamine products from the reductive pathway combine to form a variety of azaoxy dimers, such as 2,2',6,6'-tetranitro-4,4'-azoxytoluene (4,4'-Az) and in trace amounts 4,4',6,6'-tetrinitro-2,2'-azoxytoluene (2,2'-Az).\(^\text{[39]}\)

The transformation of TNT does not necessarily mean a removal of its deleterious characteristics; the primary biotransformation products of TNT, which are the dinitromonoamines 2-Am-DNT and 4-Am-DNT, have also been shown to have toxic and mutagenic effects on certain biological species. The toxicity and mutagenicity of secondary and subsequent biodegradation intermediates of TNT, such as the diaminomononitroamines 2,6-Dam-NT, 2,4-Dam-NT, and the trinitroamine TAT, have yet to be explored. Therefore, simple and accurate methods for the identification and quantitation of TNT and its biotransformation products are needed so that acceptable mass balances can be established during biodegradation.\(^\text{[100]}\)

6.2 Analytical Procedures for the Transformation Products

Several investigators have proposed and evaluated a variety of analytical methods to separate and quantitate these various products. Many of these employ either UV absorbance measurements or manipulation of the sample pH. In a very early work, Glover et al.\(^\text{[101]}\) reported both pK\(_a\) values and molar absorptivities for the two monoamine and two diamine isomers (total four compounds). Ahmad and Roberts\(^\text{[100]}\) used an Alltech Alltima RPHPLC column (RPHPLC C\(_{18}\), 25 cm × 2.1 mm i.d., 5 µm particles) with a pH gradient to resolve the analytes. A diode array detector was programmed to allow both dual-wavelength detection (at 210 and 254 nm) and compound characterization (scanning between 200–600 nm). Baseline separation of aminodinitrotoluenes could not be achieved using the method presented, which used a strict reversed-phase column, but could be achieved using either a single mixed-mode column\(^\text{[40]}\) or an LC-CN column in series with an RP C\(_{18}\) column.\(^\text{[38]}\) Ahmad and Roberts\(^\text{[100]}\) also studied the separation of the various tetrinitroazoxy-toluenes, such as 4,4'-Az and 2,2'-Az. Mobile phases consisting of aqueous buffers adjusted to three different pH values in a gradient with acetonitrile were examined for their efficiency in separating the intermediate compounds and for the minimization of speciation of the ionizable intermediates. Solvent consumption was minimized by the use of a narrow-bore column (2.1 mm i.d.). Liquid chromatography/mass spectrometry (LC/MS) supplemented with a UV detector (214 nm) has been used for detecting both the monoaminodinitrotoluenes and 2,4-Dam-NT in the urine of rats fed TNT and the same analytes plus 2,6-Dam-NT in human TNT workers.\(^\text{[102]}\) TNT and its principal metabolites were studied by direct injection electrospray ionization/mass spectrometry (ESI/MS).\(^\text{[103]}\)

Several investigators have reported procedures in which the transformation products of TNT are analyzed using either GC/ECD or GC/MS, rather than HPLC. For example, Huang et al.\(^\text{[104]}\) described a procedure for quantitating 2,6-Dam-NT in urine. Samples were initially neutralized with sodium bicarbonate, then extracted with toluene which was subsequently dried with anhydrous sodium sulfate. Quantitation of the underivatized analyte was performed using GC/ECD. Mußmann et al.\(^\text{[105]}\) described a special procedure for the dinitronitrotoluenes in which the
pH of an aqueous sample was initially adjusted to 12. After batch extraction with dichloromethane and extract concentration, the analytes were derivatized with heptafluorobutyric anhydride (HFBA) or N-methyl-bis(trifluoroacetamide) (MBTFA), then separated and detected using GC/ECD. Schoene et al.\(^{(106)}\) observed that derivatizations of the TNT metabolites and transformation products performed with \(N\)-(tert-butyldimethylsilyl)-N-methyl-trifluoroacetamide (MTBSTFA) were frequently incomplete. More satisfactory results were obtained when MTBSTFA derivatizations were supplemented with MBTFA, as noted above. Detection and quantitation of the derivatized analytes were performed using a gas chromatograph equipped with either a mass-selective detector (MSD) or atomic emission detector (AED).

### 6.3 Experimental Evidence for the Three Transformation Pathways

Caton and Griest\(^{(40)}\) demonstrated clearly that the microbial transformation of TNT in composting material is strongly time-dependent; products both “grow in” and “die out” with time. The two monoaminodinitrotoluenes were observed in both the fresh composts and their leachates. The two dianaminodinitrotoluenes “grew in” as the monoaminonitrotoluenes decreased in abundance during the course of composting, and then decreased further as composting continued. Except for one of the azoxy dimers (4,4’-Az) in leachates prepared from soils in the early stages of composting, no other transformation products or reduction/oxidation metabolites of TNT (or HMX and RDX) were observed.

Jenkins and Walsh\(^{(2,107)}\) evaluated eleven samples of authentic contaminated soils taken from six independent remediation sites for the presence of TNT transformation products. The concentration of the parent TNT in soil ranged from 1\(\mu\)g g\(^{-1}\) to 14 mg g\(^{-1}\). Subsamples were extracted with acetone and analyzed by GC/MS. The most common transformation products were 2-Am-DNT and 4-Am-DNT, the initial microbiological reduction products of TNT. TNB, a photodecomposition product of TNT, was identified in 5 out of the 11 soils. Other transformation products identified in 4 out of the 11 soils were trinitrobenzaldehyde (TNBA), and 3,5-DNA. TNBA, like TNB, is a photodecomposition product of TNT, and converts to TNB by decarbonylation (loss of carbon monoxide from the aldehyde). 3,5-DNA is a microbiological reduction product of TNB. The conversion of 3,5-DNA from TNB in soil is consistent with the formation of 2-Am-DNT and 4-Am-DNT from TNT in soil.\(^{(5)}\)

Caton et al.\(^{(108)}\) investigated the transformation of explosives by common marine micro-organisms. Cultures of Vibrio, Amphora, or Skeltonema were exposed to carbon-14 labeled or unlabeled TNT or RDX coated on steel plates in micro-aquariums to simulate the leaching and transformations of explosives from unexploded ordnance, and the reactions and partitioning of the explosives were followed using HPLC and liquid scintillation counting. TNT was transformed into the same metabolites as have been observed in the composting studies. The water-soluble mono- and diamino-metabolites of TNT were observed in the aqueous phase, while the sparingly soluble (ca. 1 ppm) azoxydimers preferentially accumulated in the particulate phase. In contrast, RDX did not transform appreciably during the experiment, and it accumulated in the aqueous phase.

Hawari et al.\(^{(109)}\) evaluated the biotransformation of TNT in anaerobic sludge supplemented with molasses using a combination of SPME/GC/MS and LC/MS. This work confirmed the existence of the reductive pathway, in which the end product is TAT. Under biotic conditions at pH 7.0, TAT is converted according to the condensation pathway first to azoxy dimers and later to polymers. In contrast, under abiotic conditions at pH 2–3, TAT is converted to stepwise to a variety of hydroxydiamine and dihydroxylamine isomers, ultimately yielding 2,4,6-trihydroxytoluene. The biotransformation of TNT to the various reduction products is very rapid, yielding almost complete disappearance of TNT within three hours. The production of TAT increases monotonically for at least seven hours.

Thorne and Leggett\(^{(99)}\) hypothesized that reduced TNT products were covalently bound to matrices containing considerable quantities of organic matter, such as composted soil. They exhaustively extracted samples of this matrix contaminated with TNT under three distinct conditions, viz. (a) acetonitrile (removal of all unbound TNT and its reduction products); (b) 50% aqueous sulfuric acid; and (c) 0.5 M sodium hydroxide followed by concentrated sulfuric acid. The authors noted that after 40 days of composting, very little of the amino and diamino reduction products were released by acid hydrolysis. The acid hydrolysis did degrade the matrix substantially, but did not release additional TNT, even though the analyte is stable under the extraction conditions. When the composted soil samples were subjected to an initial base hydrolysis, the quantities of amino and diamino compounds released were roughly equal to those released by the acid-only hydrolysis. However, the subsequent acid hydrolysis of these base-treated samples released considerably more of the reduction products. The authors postulated that the transformation of TNT to solvent nonextractable reduction products appeared to go through two stages of covalent binding to the compost matrix. In the first stage, a significant percentage of the bonds are hydrolyzable by
acid alone or a combination of base and acid. As composting continues, a second stage occurs in which either the bonds are altered to form different functional groups that are nonhydrolyzable or additional bonds form as the bound transformation products are further reduced. This process may result in the potential for long-term releases of TNT metabolites that might not occur if composting is continued into the second stage of nonhydrolyzable binding.

7 DETECTION OF EXPLOSIVES IN AIR

7.1 The Challenge of Detecting Pure Explosive Vapors in Air

The challenge of detecting explosives in the environment is compounded substantially when the sample matrix is air, rather than soil or groundwater. The equilibrium vapor phase concentration of most explosives at 25°C ranges between 6 and 18 parts per trillion for RDX and PETN, respectively, to 9.4 and 580 parts-per-billion for TNT and NG, respectively—a range of nearly eight orders of magnitude.\(^{110}\)

Fetterolf\(^{110}\) noted that attempts to detect pure explosive vapors, particularly in a forensic setting, often fall short of expectations.

Consider the scenario of a briefcase containing a small amount of plastic explosive such as C-4 (RDX). A simple calculation, using Boyle’s gas laws and the equilibrium vapor pressure of pure explosives at standard temperature and pressure, shows that a standard-sized empty briefcase (10.6 L) would contain only 6.3 \(\times\) \(10^{-13}\) g or 5.94 \(\times\) \(10^{-14}\) g L\(^{-1}\) RDX vapor. This is, however, the best that one can expect. In reality, the amount of explosive vapor available for analysis is much less. These simple calculations fail to take into account Raoult’s Law, which states that the true vapor pressure of the explosive will be reduced because it is a component of a mixture. Another factor to be considered is the kinetics or time dependence associated with vaporization and the absorption of explosives on surfaces. TNT has been shown to vapor deposit on a variety of surfaces. Griffy’s kinetic model of explosive vapor concentration estimated that until a monolayer of TNT was deposited on the surrounding walls of a room, the vapor pressure was 6 \(\times\) \(10^{-4}\) less than the equilibrium vapor pressure. The practical implication of this result is that explosive detectors which function by collecting air samples are unlikely to be effective unless their sensitivity is orders of magnitude greater than that required to detect equilibrium amounts of the vapor. Finally, the emission rate of explosives from the concealment device must be taken into account. Lucero has estimated that this is approximately 1 mL/min. The emission rate of the explosive is also affected by any barrier material, (e.g. plastic wrap or foil) wrapped around it. [Reproduced by permission of the CRC Press © 1995 from D.D. Fetterolf, ‘Detection and Identification of Explosives by Mass Spectrometry’ in Forensic Applications of Mass Spectrometry, ed. J. Yinon, 240–241, 1995.]

Taken together, the physical limitations of the problem dictate that only the most sensitive analytical detection processes will be capable of detecting explosive compounds in air. Some of these are described in the following sections.

The ability to generate explosive vapors of known concentration is a critical concern for calibrating and testing any device used in the sampling of air for the presence of nearby explosives. For example, the Independent Validation and Verification (IV&V) facility (Explosives Detection Systems, a branch of the Federal Aviation Administration at Idaho National Engineering Laboratory) required pulses of explosive vapors between 1 and 1000 pg in less than 5 seconds with a high degree of accuracy. Furthermore, the mass output had to be varied during a test with only a few minutes between pulses. Davies et al.\(^{111}\) designed and tested a device which employed a heated coil packed with a support containing the desired explosive. The generator was capable of producing pulses of TNT, RDX, or PETN with well-defined concentrations. A typical vapor generator calibration was performed at a fixed coil temperature and pulse width (5 seconds in this study) with the mass output varied by changing the carrier gas flow rate and/or pulse width. Varying the coil temperature to adjust the vapor generator mass output was not feasible in the IV&V tests because of the lengthy equilibration time required to reach a steady-state saturated vapor concentration.

7.2 Canine Detection of Explosives in Air

The traditional method for detecting explosives in air has been the use of canines trained to recognize the “scent” of these compounds. A major advantage of dogs is their mobility, a significant improvement over fixed detector installations, which need only be circumvented by a terrorist placing a bomb or smuggling explosives.\(^{112}\) The use of canines, while widely practiced, exhibits several major drawbacks and concerns. The greatest of these is that there is no objective unbiased understanding of exactly how the dog senses the presence of explosives. Unlike machines, dogs do not come with precise specifications, including detection limit, probability of detection, mean time between failure, etc. Many internal and external factors can affect canine olfaction, including heat stress, toxins, injury, and even disease at pre-symptomatic stages. There’s no “press-to-test” button for a dog to check if the “system” is working effectively—a major disadvantage.\(^{113}\) In spite of these apparent disadvantages, trained canines may fulfill many of the missions assigned to instruments both
more effectively and at lower cost. A major advantage of dogs is that they actually locate suspicious items; at present, machines can only verify the presence or absence of explosives.

A dog’s supposed “supersensitivity” is a myth. Rather, the dog’s accurate and discriminating detection ability make it invaluable. It has never been demonstrated conclusively exactly what causes a trained dog to respond – and, similarly, what causes a false-positive alarm in a dog. A clear understanding of odor signatures should help explain false-positive responses. People have reported bomb-sniffing dogs “alerting” on materials unrelated to explosives. In such a situation, more dogs are brought in to sniff the material. If all the other dogs also alert, one concludes that it might be something which, to the dogs, “smells” like explosives. It doesn’t mean the dog is wrong. The dog may have detected the odor it was trained to smell, but the “scent” may be coming from some other material that has the same odor signature as the target substance. For example, a dog trained to look for explosives based on ammonium nitrate may alert at the “scent” of ammonium nitrate in garden fertilizer.

Strobel et al.\(^{112}\) estimated that there are over 19 000 known explosives compositions worldwide. For that reason, it is impractical to condition a dog to alert correctly for each. Nevertheless, the vast majority of explosives are composed of a relatively small number of chemical compounds or ingredients. For that reason, the Bureau of Alcohol, Tobacco, and Firearms have evaluated a new program in which dogs are trained only with pure explosives.\(^{112}\) In this way, a trained dog should recognize any formulation containing that particular component.

### 7.3 Mass Spectrometric Detection of Explosives in Air

There has been a long-standing interest in an instrumental approach for trace explosives detection both as a complement to canine olfaction and as a means for explosives detection in scenarios in which canine olfaction is either impractical or inappropriate. For the detection of explosives vapors, gas-phase ionization techniques are the methods of choice. A variety of such methods has been applied to the analysis and detection of explosives vapors, including electron ionization, CI, field ionization, atmospheric pressure ionization, low-pressure electron capture, and atmospheric sampling glow discharge ionization (ASGDI). In general, ASGDI\(^{114}\) is a simple and rugged means for ionizing organic species. The response is essentially instantaneous, with very little memory effect arising from analyte species that enter the ionization region. Chemical noise arising from the analyte deposited within the ionization volume, which ordinarily requires extensive and time-consuming cleaning with other sources, poses few problems even after many months of nearly continuous operation.

The analysis of negative ions in the explosives detection application is employed because, unlike most compounds in nature, explosives readily form anions. Several other approaches to explosives vapor detection take advantage of this characteristic, including IMS, atmospheric pressure ionization mass spectrometry, and GC/ECD.

Certain physical properties of the ASGDI in particular make it the ideal mass spectrometric source for the detection of explosives in air:

- It exhibits a simple and rugged design which provides a direct interface between the atmosphere and the vacuum system of the mass spectrometer. The ASGDI has no filaments or discharge needles to replace and can be operated continuously for months without maintenance. Despite rather extensive ion burning, source cleaning is not important. Some of the ion sources have been operated over the course of several years without cleaning and show no loss in performance.
- Its high throughput leads to rapid response and pump-out of analyte and minimized memory effects.

The ion-trap mass spectrometer (ITMS) can accumulate selected ions prior to detection; hence, it has the capability of detecting ultratrace concentrations of explosives in air. McLuckey et al.\(^{115}\) coupled an ASGDI with an ITMS and challenged the new instrument with air containing low parts-per-billion concentrations of TNT. In order to improve the detection capabilities of the instrument still further, both NICI and tandem mass spectrometry were employed. The signal observed at \(m/z\) 227 (negative ion mass spectrum) corresponded to the molecular anion from ca. 100 fg TNT. The instrument described has proved to be capable of detecting organic explosives in air at the parts per \(10^{12}\) (trillion) level.

The sensitivity and selectivity of ion-trap mass spectrometric measurements of explosives can be improved substantially by including a filtered noise field (FNF) as part of the ion collection process. FNF is a form of mass-selective ejection, in which undesired masses are removed from the mass spectrometer, and the desired masses are retained, collected, and amplified. When a FNF is applied during ion accumulation, interferences in the desired mass spectra are reduced significantly, and the desired ions, defined by frequency “notches”, stand out very clearly and cleanly.\(^{116,117}\) In FNF, a basic waveform having evenly spaced (typically 250, 500, or 1000 Hz) frequency components spanning the frequency spectrum of the entire ion-trap mass/charge range is synthesized digitally. Subsequent digital processing permits the waveform to be shaped so as to effect mass-selective accumulation

\[ m/z \]

\[ \text{Atmospheric pressure glow discharge ionization} \]
(via mass-selective ejection). Moreover, the user can optimize the FNF signal characteristics interactively. Two literature examples illustrate the power of FNF technology: (a) the clean determination of TNT, RDX, and PETN in air at sub parts-per-billion concentrations; and (b) the determination of TNT and the polysulfur ion clusters \((S_2\times), (S_3\times), \text{ and } (S_4\times)\) in black powder. McLuckey et al. have also applied random noise intentionally to the end caps of an ion-trap as a means of improving the overall selectivity of the device.

Fetterolf discussed the application of IMS to the detection of explosives in air; previous sections in this chapter have described its application to water and soil matrices. In general, IMS possesses many of the desirable analytical figures of merit of conventional laboratory-based instruments such as good sensitivity, selectivity, and speed of analysis. They are often simple and small to operate. This ease of use and portability permit operation in real world scenarios not only as a forensic tool but also as an investigative tool. The Barringer IONSCAN Model 200 was evaluated as a “typical” IMS instrument. In the reaction region, atmospheric pressure carrier gas (purified air), hexachloroethane \((C_2Cl_6)\), the reactant gas, and 4-nitrobenzonitrile, an internal calibrant are ionized by a \(^{60}\text{Ni}\) beta emitter to form \(\text{Cl}\text{-ions}\). The use of modified ion chemistry to improve the sensitivity and selectivity of the detection by IMS is quite common. The reactant ions can then undergo one or more ion/molecule reactions with an explosive molecule. In general, negative ionization provides a high degree of selectivity, as discussed earlier. The formation of multiple species greatly increases the specificity and reduces the possibility of false positives since the peak detection algorithm must recognize two of the three peaks for RDX, PETN, and NG before the audible alarm will sound. In one set of experiments, a subject deliberately touched C-4, an RDX-containing explosive, then subsequently touched various parts of an automobile. Samples were collected before and after the contact transfer from each of the touched areas of the car and from the subject’s hands by vacuum onto a Teflon filter disk. An alternative sampling method which has also proven successful is to simply wipe the suspected surface with the sample collector. Careful procedures were followed to ensure that no cross-contamination occurred by verifying that both the sample disks and the IMS were clear of explosives before sample collection. The car surfaces and hands were negative for RDX prior to touching the explosive, but showed easily detectable RDX residue after contact with C-4. In a separate experiment, after handling C-4, eight consecutive hand washes with soap and water were required before the IMS could no longer detect the RDX. Experiments involving the IMS frequently demonstrate presence or absence of a given explosive rather than providing quantitative information.

Fetterolf has reported the detection limits (criterion not specified) for TNT, RDX, PETN, and NG as 200, 200, 80, and 50 pg, respectively for at least one of the ions formed in the IMS.

Gieray et al. and Reilly et al. have reported a mass spectrometric method capable of characterizing individual airborne particulates of uranium oxide or diesel engine smoke. The same system was evaluated for real-time mass spectrometry of individual airborne and waterborne explosives particles. Samples of TNT, RDX, and PETN were analyzed on individual particles generated from suspensions of micrometer-sized particles in water, or from solution in acetone. Suspensions and solutions were nebulized and the resulting droplets dried and introduced into the ITMS. When individual particles arrived at the center of the ion-trap, a focused XeCl \((308 \text{ nm})\) or ArF \((193 \text{ nm})\) laser was used to both ablate and ionize material from the particle. Once the particulate matter was ionized, it was analyzed using a variety of ion-trap-based mass spectrometric methods. Negative ion mass measurements of the three explosives clearly show that acetone, but not water, is involved in the observed spectra obtained using the XeCl excimer laser. Furthermore, PETN particles apparently decomposed when ablated by the XeCl laser pulses, yielding mostly nitrate ions at \(m/z\) 62. PETN was also studied with an ArF laser at 193 nm, where the analyte absorbs strongly with little absorption at 308 nm. The work demonstrated that it was possible to generate mass spectra of individual micrometer-sized particles of TNT, RDX, and PETN, either as aqueous suspensions, as dry airborne particles, or as particles nebulized from solution. Preliminary estimates of method sensitivity were not presented.

7.4 Additional Procedures for Explosives in Air

Jenkins and Walsh discussed the determination of explosives in air using SPME fibers as collection devices. Polydimethylsiloxane/divinylbenzene fibers were particularly efficient at collecting vapors of the isomers of DNT, DNB, and TNT. The use of this technique, combined with GC using a new micro ECD, has resulted in the ability to detect many of these energetic chemicals below 1 picogram, with concentration detection limits as low as \(10^{-14} \text{ g mL}^{-1}\) of air.

8 ADDITIONAL PROCEDURES FOR THE DETERMINATION OF EXPLOSIVES

The procedures which have been discussed in this chapter have been developed using bona fide environmental
matrices, viz. air, groundwater, soil, and compost. A large body of literature exists which describes the detection of explosives in solutions or unusual samples such as hand swabs used in forensics analysis. Some of these procedures will be mentioned here to indicate additional analytical tools available for detecting these compounds in the environment.

8.1 Procedures Featuring Chemiluminescent Nitrogen Detection of Explosives

The use of CLND for the gas- or liquid-chromatographic detection of explosives was mentioned earlier. For many years, the only CLND device available was the “TEA”, a product of Thermo Electron Corp. For this reason, the two acronyms are frequently, but inaccurately, used synonymously.) Several investigators have expressed a preference for the ECD because of the latter’s greater sensitivity. The CLND exhibits greater selectivity towards nitro-containing compounds and is more tolerant of matrix interferences than the ECD. For that reason, the degree of extract cleanup required is frequently reduced. The explanation for both of these features lies in the three-step operating mechanism of the CLND: (a) combustion of the analyte at 900–1100°C to form NO, carbon dioxide, water, and other oxides; (b) reaction of NO with ozone to form “excited state” NO₂; and (c) relaxation of NO₂ back to ground state NO₂ with the emission of a photon of light in the near-infrared.

In general, GC of explosives requires short (typically 6 to 12 m) narrow-bore (250µm diameter) columns, compared to more commonly used dimensions of 30 to 60 m and 320 to 530 µm, respectively. Thin films are preferred to reduce peak broadening caused by low diffusion velocities. The TEA must be operated in its “total nitrogen” mode, in which the furnace temperature is frequently 900 to 1000°C, to combust the analytes and convert all nitrogen present to nitrogen oxides.

The dead volume of the TEA or CLND is typically greater than that of a contemporary ECD; hence, some additional peak broadening should be expected when the chemiluminescence detectors are employed.

Douse described the characteristics of a capillary supercritical fluid chromatograph equipped with a CLND. The analytes were eluted through a short nonpolar column (6.8 m × 0.05 mm i.d. SB Octyl 50 Superbond cross-linked flexible silica capillary, 0.25µm film thickness) with supercritical carbon dioxide (no modifier). Minimum detectable levels (not defined) ranged from 20 to 60 pg for a representative group of compounds: NG (23 pg); PETN (40 pg); tetryl (60 pg); HNBB, hexanitrobenzyl (55 pg). Compounds containing very polar functional groups, e.g. amino (polynitrophenylamines and nitroguanidine) and hydroxy (PA, styphnic acid, and NC) could not be analyzed. In addition, HMX exhibited poor peak shape, probably due to its low solubility in supercritical carbon dioxide. The use of organic modifiers or a more polar supercritical fluid might improve the chromatographic analyses of these compounds. The author noted that some explosives which cannot be analyzed by capillary GC, due to their involatility or instability, were readily analysed by capillary SFC. In addition, capillary SFC/TEA appeared to be more resistant than capillary GC/TEA to contamination by coextractives.

Kolla et al. also noted that the efficiency of SFE, which may be used to extract explosives from soils and related samples, depends not only upon the chemical nature of the analyte but also on the nature of the supporting surface. The influence of the matrix was studied by spiking soils of different carbon content with PETN and NG. The recovery of NG drops steeply if it is mixed into soil of a high carbon content. The recovery of PETN is less influenced than NG by the carbon content of the matrix. If soils with a high humus content are tested, higher pressures and longer extraction times than usual are recommended. As the polarity of the explosive analyte decreases, its retention time from reversed-phase columns increases and its recovery rate in SFE improves. This effect is explained by the increased solubility of nonpolar explosives in the nonpolar supercritical carbon dioxide medium.

In a very recent paper, Bailey et al. described the separation of explosives using capillary electrochromatography (CEC). This can be viewed as a hybrid technique between HPLC and capillary electrophoresis. In CEC, neutral species are separated on the basis of differential partitioning between the mobile and stationary phases, while charged species are additionally separated according to differences in electrophoretic mobility. Under isocratic conditions, using capillaries packed with ~20 cm of 1.5 µm nonporous octyldecysilica particles and moderate electric fields (<1000 V cm⁻¹), baseline separations of all 14 of the Method 8330 components were achieved in under 7 min. Using shorter columns and stronger fields, 13 of the 14 components were separated in less than 2 min. These analysis times represent major improvements in turnaround time compared to the traditional HPLC methods, which typically require 30 min per determination or more. The addition of modifiers such as sodium dodecyl sulfate and/or 2-(N-morpholino)ethanesulfonic acid monohydrate reduced tailing in the analyte peaks.

8.2 Procedures Featuring Mass Spectrometric Detection of Explosives

The reason for the outstanding sensitivity of the ECD towards certain explosives is the electron-capturing
nitro groups (up to four) on a given analyte. These same electron-capturing properties also make explosives amenable to highly-sensitive and selective mass spectroscopic detection featuring NICI, which can permit greater selectivity and sensitivity than the more traditional and general EI ionization. The mass spectrometer in a given ionization mode is usually coupled with a gas, liquid, or supercritical fluid chromatograph both to separate co-extracted interferences from the analytes and to improve resolution of the explosives from each other and matrix components.

Mass spectra were obtained for several explosives (TNT, tetryl, NG, PETN, RDX) using “direct exposure CI mass spectrometry”, a form of NICI, with isobutane as the reagent gas.[133] Similar data appears for TNT, NG, PETN, RDX, and HMX using NICI with isobutane as the reagent gas in two additional references.[134,135] A detailed discussion of the EI and CI spectra of explosives is given elsewhere.[136,137]

Huang et al.[138] discussed the application of SFC and Mass Spectroscopy (MS) to the determination of explosives. The application of SFC/MS under EI conditions has been reported; however, it is more difficult to achieve EI conditions in an SFC/MS, compared to a GC/MS system. CI, therefore, is the most common ionization method for SFC/MS. Methane, ammonia, isobutane, and the supercritical mobile phase itself frequently have been used as the primary reagent gases to generate positive-ion CI mass spectra. The columns employed are frequently short (3 and 6 m), narrow bore (50 and 25 µm internal diameters), with a thin film (0.25 µm thickness 25% biphenyl polysiloxane or SE-54 stationary phases). The supercritical mobile phase is carbon dioxide doped with either methane or ammonia. Four nitroaromatics, viz. 2,6-DNT, 2,4-DNT, TNT, and TNB were evaluated; the molecular ion was detected. Detection limits observed in the NICI mode were 200 pg (TNT), 1 ng (RDX, HMX, PETN), 5 ng (tetryl), and 50 ng (AP).

ESI (electrospray ionization) is a sample introduction procedure for HPLC which produces charged droplets in the ion source capable of ionizing species such as explosives. Yinnon et al.[139] used such a system in the study of TNT, RDX, HMX, tetryl, PETN, NG, EGDN, and Semtex. The test compounds were eluted isocratically from a short minicolumn (Keystone ODS Hypersil column, 15 cm × 2 mm i.d., 3 µm particle size) with either methanol–water (1:1) or acetonitrile–water (70:30) at 150 or 200 µL min⁻¹, respectively. Mass spectra were obtained in the NICI mode using a Finnigan LCQ ITMS. Standard solutions containing TNT, tetryl, RDX, HMX, and PETN were prepared, and aliquots were injected into the HPLC/MS system. The resulting responses were used to calculate the LODs. The mass spectrometer was operated in the selected ion monitoring (SIM) mode, using characteristic ion or ions for each compound, to provide enhanced sensitivity. The criterion for estimating the LODs was the smallest amount injected that yielded a signal-to-noise ratio greater than 3 for the mass chromatogram of the characteristic ions. LODs were found to be between 5 to 10 pg, corresponding to 1–2 ng mL⁻¹ in solution.

Tamiri and Zitrin[140] employed short-film fused silica capillary columns in their measurement methods, which featured mass spectroscopic detection using both EI and CI (reagent gas methane). NG, 2,4-DNT, TNT, PETN, RDX, and tetryl emerged as well-resolved peaks. PETN and RDX occasionally failed to elute from longer (30 m) columns; hence, the shorter 15 m columns were preferred. Tetryl routinely degraded partially in the ion source to the stable well-characterized product N-methylpicramide, which was frequently used to confirm the presence of tetryl.
8.3 Procedures Featuring Nontraditional Analytical Methods

Some of the most promising new analytical methodologies for detecting explosives in environmental or forensic materials are various magnetic resonance methods which are still in their infancy. For example, hydrogen transient nuclear magnetic resonance (HTNMR) has been found to be particularly useful for the practical detection of most explosives concealed in letters, parcels and baggage. The technique might therefore be applicable for soils. Explosives exhibit HTNMR signal relaxation properties that are different from most other common materials. This feature is absolutely essential to the successful application of this method for inspection since the vast majority of nonmetallic materials contain hydrogen and produce strong hydrogen nuclear magnetic resonance (NMR) signals. Additionally, selectivity is provided in HTNMR by the $^1$H-NMR to $^{14}$N-nuclear quadrupole resonance (NQR) level crossing effect. This provides useful selective signature data for some explosives and is also effective in drastically reducing the analysis time. The unique HTNMR signal relaxation properties have been found to be characteristic for almost all explosives of concern. This includes the high-energy military explosives as well as the more common commercial explosives such as dynamites and water gels used in civilian construction, excavation, and mining activities. Detection is accomplished through magnetic and electromagnetic fields used to sense the hydrogen contained within the materials of the item to be inspected. By analysis and processing of this total hydrogen NMR signal, any contribution to the response produced by hydrogen in explosives can be separated from that produced by the hydrogen in most other materials. Through this procedure the HTNMR response has been found to be useful for rapidly and selectively detecting NG-based dynamites, water gel explosives, C-4 (plastic explosives), RDX, TNT, PETN, smokeless powder, and most other high-energy and commercial explosives and propellants. Results of several thousand tests have demonstrated the general suitability of the HTNMR method for baggage, letter mail, and parcel inspection and have shown a high detection probability and a low rate of false alarms.

Buess et al. discussed the application of $^{14}$N pure NQR to the detection of RDX in various samples. RDX was an ideal target compound because it is not only an ideal NQR model compound, but it is also widely used in military applications. NQR is a particularly attractive approach to the problem of explosives detection, because the $^{14}$N NQR absorption frequencies from crystalline materials are virtually unique. Hence, by looking for the nitrogen signal at, for example, the NQR frequency of RDX, only those nitrogens in RDX will be detected. Therefore, interferences are not expected with an NQR explosives detector. A literature search of the 10000 compounds that have been examined by NQR failed to show any other NQR resonances sufficiently near to those of RDX that would constitute a plausible interference. This specificity feature should be contrasted with nuclear-based techniques, for which all nitrogen cross-sections are the same, independent of the chemical composition of the material. Subsequently, NQR would determine the presence of other classes of explosives, (e.g. PETN) by examination at the corresponding NQR frequency for PETN. In principle, such examination could be performed essentially simultaneously with the RDX inspection. NQR is the examination of nuclei with nuclear quadrupolar moments in the absence of a static magnetic field. Hence, in addition to its specificity, a second advantage of NQR is that no magnet is required, in contrast to NMR methods. For that reason, potential damage to magnetically recorded material is avoided; there is no exposure of large, static magnetic fields to personnel. Because a magnet is not required, the costs are lower than for an NMR system. Furthermore, NQR uses nonionizing radiofrequency (rf) radiation, whereas nuclear techniques employ ionizing radiation. There are some inherently unattractive features of NQR which must be addressed before an NQR explosives detector can be marketed commercially. For example, NQR signals are weak and are generally below the level determined by the random electrical noise in the rf coil which detects the signal. The signal-to-noise ratio is increased by repeating the experiment as rapidly as possible and adding up the results; the signal-to-noise ratio improves by the square root of the number of repetitions.

9 SUMMARY AND CONCLUSIONS

The interest in analytical procedures for explosives residues in environmental media steadily increases as more and more formerly utilized military sites are certified and converted to full- or part-time civilian use. Careful statistical studies have clearly demonstrated that analyses based on randomly-collected “grab” samples of soils frequently produce a false picture of the extent of explosives contamination. Well-designed sampling plans, which employ multiple samples taken from small areas and which consider the distribution of the soil particles, are mandatory for understanding the true extent of contamination. Because site remediation is such a costly venture, there is a strong need for analytical procedures which are capable of quantitating explosives.
in soil and groundwater samples quickly and accurately, using equipment and methods which may be operated reliably by nontechnical personnel. For that reason, scientific interest is gradually moving away from the completely laboratory-based, statistically validated, and highly technical standardized methods, such as HPLC and GC and their mass spectroscopic analogs, towards the many fieldable analytical techniques. Some of these, such as ion mobility spectrometry and the various magnetic resonance techniques, are still in their infancy; their potential and utility are still to be fully developed. Others, such as the colorimetric and enzyme-based field test kits, have been fully tested and, in some cases, have been adopted as standard methods themselves. Still others, such as the various mass spectrometric methods, involve highly technical equipment which must be simplified before it can be used routinely in the field. However, the extreme sensitivities characteristic of these state-of-the-art instruments partially offset the need for extensive operator training. A variety of mass spectrometric techniques may yet be used routinely for explosives residue analysis in the field. Some of these new methods may be used in, or even be derived from, forensic applications.

ACKNOWLEDGMENTS

The author gratefully acknowledges the assistance and suggestions of Dr. Wayne H. Griest (Chemical and Analytical Sciences Division) and Drs. Sylvia S. Talmage and Annetta P. Watson (Life Sciences Division), all of the Oak Ridge National Laboratory, during the preparation of this manuscript. The author also acknowledges Dr. Thomas F. Jenkins, US Army CRREL, for kindly providing many of the CRREL documents which were cited in this chapter. Research was sponsored by the US Army’s Rocky Mountain Arsenal pursuant to an Interagency Agreement with the US Department of Energy (DOE), DOE No. 1989-H077-A1. This article was prepared by Lockheed Martin Energy Research Corporation as the Management and Operating Contractor for DOE’s Oak Ridge National Laboratory, under federal contract no. Atomic absorption spectrometry (AAS) is one of the most often used techniques for the quantitative determination of elements in environmental materials at trace and ultratrace levels. AAS is an optical atomic spectrometric technique based on the measurement of the specific absorption originating from free nonionized atoms in the gas phase. To transfer the analyte to free atoms and provide the hostile environment for these atoms at least for a short moment, different types of atomizer are in use. A scheme of the principle components of an AAS instrument is given in Figure 1.

In FAAS, flames with different fuel–oxidant combinations are used for atomization, whereas in electrothermal atomic absorption spectrometry (ETAAS) different types of electrothermal atomizers are used, such as the graphite tube furnace in GFAAS or the quartz tube atomizer (QTA) in hydride generation atomic absorption spectrometry (HGAAS). These atomizers are meant to provide just the necessary energy via a chain of reactions to transfer the sample into atoms. Most of these atoms are in their electronic ground state with energy, $E_0$, and are able to absorb energy ($\Delta E = E_1 - E_0 = h\nu = hc/\lambda$) from a radiation source (lamp), where $E_1$ is the energy of the (first) excited state, $h$ is Planck’s constant, $c$ is the velocity of light and $\nu$ and $\lambda$ are the frequency and the wavelength of the atomic spectral line, respectively. The probing beam from the radiation source passes through the observation volume of the atomizer, wherein the radiation is absorbed by the cloud of atoms, which are
where $T$ absorbance, spectrometer and processed to yield the analyte signal, $I$ and the power transmitted through the absorption volume. The ratio of the incident radiant power, $I_0$, and the power transmitted through the absorption volume, $I$, is then determined by the detection system of the spectrometer and processed to yield the analyte signal, absorbance, $A$ [Equations 1 and 2]:

$$A = \log_{10} \frac{I_0}{I} = -\log_{10} T$$  \hspace{1cm} (1)

$$A = abc \quad \text{(Beer’s law)} \hspace{1cm} (2)$$

where $T$ is the transmittance, $a$ is the absorptivity, $b$ is the thickness of the absorption volume and $c$ is the concentration of the absorbing analyte atoms. The relationship between the concentration of the analyte in the sample, $c_{\text{sample}}$ and the concentration of the analyte in the absorption volume, $c$, is normally established via a calibration graph [Equation 3]:

$$c_{\text{sample}} = f(A)$$  \hspace{1cm} (3)

The very high selectivity of AAS originates from the simplicity of the absorption spectra, where only a limited number of lines limits the chance of cases of spectral interference, and the use of line sources that emit just the radiation specific to the analyte, such as the hollow-cathode lamp (HCL) or the electrodeless discharge lamp (EDL). Multi-element HCLs are available, but should be used with care, because of the reduction in selectivity due to the possibility of spectral interferences.

The role of the spectrometer in this configuration is limited to the separation of the analytical line from other lines emitted by the radiation source and from emission originating from other sources than the lamp, e.g. the atomizer itself and from emitting species inside the absorption volume. For this reason, the radiation of the lamp is modulated electronically or mechanically with a certain frequency of 50–300 Hz and the detection system is synchronized with this modulation. In order to distinguish the specific AA from other nonspecific absorption due to, for example, molecular absorption or scattering, the AA spectrometer in general uses a background correction system. Commercial instruments are equipped with at least one of the following systems: (a) deuterium background corrector, (b) halogen lamp background corrector, (c) Smith–Hiefte background corrector or (d) Zeeman-effect background corrector, the last one being the most accurate and powerful technique.\(^\text{(1)}\)

2 ATOMIC ABSORPTION TECHNIQUES AND THEIR CAPABILITIES FOR ENVIRONMENTAL ANALYSIS

2.1 Flame Atomic Absorption Spectrometry

Flames with different fuel–oxidant combinations are used for atomization in FAAS, the air–acetylene and the nitrous oxide–acetylene flames being the most popular. The air–acetylene flame generates a flame temperature of about 2525 K, is transparent over a wide spectral range and only starts to absorb radiation below 230 nm. Also, the emission of the air–acetylene flame is very low, so ideal conditions are given for most elements. Normally, this flame is operated stoichiometrically or slightly oxidizing, but it can be operated also in a reducing mode. However, in the reducing mode the lower partial pressure of oxygen is responsible for a reduced flame temperature, enhancing the risk of interference problems. Interference through ionization occurs only in a few cases, for example, for alkali metals, and can be easily avoided by the addition of an easily ionizable element as an ionization buffer, such as sodium, potassium or cesium. There are about 30 elements that in effect cannot be determined with the air–acetylene flame since they form refractory oxides, such as aluminum and silicon. Such elements require a hotter flame in order to break the element–oxygen bond, such as the nitrous oxide–acetylene flame; this flame is operated with a slight excess of fuel, providing reducing conditions and a flame temperature of about 2975 K. Both flames can be safely operated, and modern instruments contain sensors and interlocks for fully automated operation.

Samples are introduced into flames normally in the liquid form by a pneumatic nebulizer and mixed in a spray chamber with the flame gases before these reach the head of the (premixed) burner, where they are ignited. The burner has a single slot of appropriate length providing a certain depth for the absorption volume (comparable to a cuvette length), that is essential for the sensitivity of the method. Absorption of light coming from a primary light source is directed through this absorption volume and is measured at an observation height in the flame.

some millimeters above the burner exit, where the atom concentration is at its maximum. Operational parameters to control flame atomization are very few (e.g. the flame stoichiometry, the nebulizer uptake and the observation height). Typical detection limits of FAAS are of the order of 1–100 µg L⁻¹ (see Table 1) and are similar to those obtained by radially viewed inductively coupled plasma optical emission spectrometry (ICP-OES). The precision of measurements can be better than 0.3% using optimum conditions.

FAAS has found wide application in environmental analysis and is often still used as standard method. However, owing to its lack in sensitivity, its application is limited to the determination of the main and minor elements and some trace elements, especially for contaminated samples (sewage sludges, wastewater, sediments, etc.).

2.2 Graphite Furnace Atomic Absorption Spectrometry

GFAAS offers detection limits which are about a factor of 20–200 lower than for FAAS (see Table 1). This significant improvement is the result of the improved residence time of the atoms in the absorption volume, which is mainly dictated by diffusional losses from the tube. In principle, the much longer residence time should also lead to greater freedom from interferences, provided that atomization takes place under isothermal conditions. To come as close as possible to the ideal state of isothermal atomization, different efforts have been made, of which platform atomization is the most prominent. Platform atomization together with the use of a powerful Zeeman effect background correction (ZBC) system, fast signal evaluation and the application of matrix (chemical) modification, forms the basis of the stabilized temperature platform furnace (STPF) concept.³ A step even further in this direction is the transversely heated graphite atomizer (THGA), which heats uniformly over the whole tube length avoiding any cold spots,⁴ which are observed in longitudinally heated furnaces, owing to the necessity for cooling the tube ends for reasons of reproducible electrical contact.⁵

The disadvantage of GFAAS compared with FAAS is the lower sample throughput. In a graphite furnace system the measurement cycle starts with the injection of liquid samples (digest, extract, suspension, standard solution) of about 5–50 µL into the graphite tube or into the cavity of a platform. Thereafter a temperature program is initiated, including drying, pyrolysis (thermal pretreatment for the decomposition of organic matrix or the volatilization of other matrix components), atomization (with temperatures up to 2800 °C), and an additional cleaning step to remove remaining matrix components from the furnace. The whole cycle takes typically about 50–100 s (i.e. about 10 times a regular FAAS measurement) and must be optimized for a particular analyte–matrix combination. During the steps of this cycle the furnace is flushed with an inert purge gas stream (argon is recommended) in order to protect hot graphite.
parts against oxidation and to remove volatile reaction products. Other alternative gases such as air, oxygen and hydrogen can be added during the first steps, in order to facilitate thermal pretreatment. GFAAS is called a mature technique, not only with respect to instrumentation, but also with respect to methodology. Using STPF conditions together with integrated absorbance for signal evaluation, it can be shown that the characteristic mass (i.e. the mass of element in picograms that produces an integrated signal equivalent to 0.0004 A s) for various elements in different matrices differs by only around ±15% between different instruments, offering a way towards standardless analysis (sometimes even called ‘absolute analysis’). At least such possibilities can be used for semiquantitative analysis for screening purposes and for system diagnosis. With respect to environmental analysis, GFAAS is the standard method for many trace elements, especially for background values, and for unpolluted samples, such as fresh water and biological materials.

2.3 Other Atomic Absorption Spectroscopy Techniques

Since neither FAAS nor GFAAS offers a particular detection power for mercury and hydride-forming metalloids such as antimony, arsenic, selenium, and tin, special vapor generation techniques to measure these elements after volatilization in the gas phase were developed and are commercially available. Mercury is commonly reduced, after digestion of solid samples or directly in liquids, to elemental mercury by the addition of stannous chloride or sodium tetrahydroborate and analyzed at ambient or slightly increased temperature by the cold vapor technique with detection limits at or below the micrograms per liter level. In a similar manner, the hydride-forming elements are measured by the hydride generation technique, in which the analyte is volatilized by reduction with sodium tetrahydroborate and analyzed by atomization in a heated QTA or after in situ trapping in the graphite furnace. These different vapor generation techniques often provide detection limits improved by a factor of about 10 in comparison with GFAAS of liquid samples. Disadvantages of vapor generation techniques are the additional sources of interference during the process of vapor generation and atomization, which for the case of QTAs takes place at temperatures limited to about 1000 °C. In order to reduce the problems with vapor generation, special attention has to be paid to sample preparation, for which the requirements are the most stringent in comparison with other AAS techniques. An extensive discussion of the hydride generation technique can be found in a monograph by Dedina and Tsalev and a detailed discussion of both vapor generation techniques can be found in a monograph devoted to AAS by Welz and Sperling.

The call for automation of the vapor generation techniques was one of the driving forces behind the development of using flow injection (FI) as a sample managing system for AAS. The basic principle of using FI for the transport of sample solution for AAS is shown in Figure 2.

Nowadays the coupling of FI has been realized with all AAS techniques, including the GFAAS technique, with great benefits for AAS in many respects. FI can be used just for sample introduction in FAAS, improving the tolerance for high-salt matrices, but also can be used for sample dilution, calibration, separation, preconcentration and speciation in combination with all AAS techniques. The main advantages of FI for AAS can be summarized as its high potential for automation and its high repeatability and reproducibility of all the process. Further, FI provides a closed system, which reduces external contamination to very low levels and is operated under thermodynamically nonequilibrated conditions, which allow for high sampling rates. The ease of automation comes from the generally simple system, which normally consists of one or two independent multichannel peristaltic pumps, a multi-channel injection valve, a manifold made from polymeric tubing, flow conjunctions, mixers, reactors, separators and columns, with all the active parts under computer control. Commercial systems are available and integration of FI into the AAS software has been realized. Environmental analysis can greatly benefit from the coupling of FI with AAS in all cases where the automation reduces costly manpower or the sensitivity or selectivity of AAS alone is not sufficient for the analytical task. Examples of such applications will be briefly discussed in section 4.

Figure 2  Simplest principle using FI for the transport of measurement solution for FAAS. P1 = pump for carrier solution; P2 = pump for measurement solution; AS = autosampler; V = injection valve; B = AAS burner. (Reproduced by kind permission of Perkin-Elmer.)
3 METHOD DEVELOPMENT AND VALIDATION

3.1 The Analytical Task

Environmental chemical analysis very often is the basis of other environmental studies, such as risk assessments, or court actions, such as the withdrawal of allowances, involving decisions which have an enormous economic impact. In order for analytical results to provide the information necessary to support such decisions, confidence in the quality of the analysis must be sufficiently high. Those parameters that will influence the decisions, the data quality objectives (DQO) should be defined, in order to fit the analysis for the purpose. Two basic parameters should be considered when discussing analytical results: accuracy (closeness of the agreement between the result of a measurement and a true value of the measurable quantity of an analyte) and uncertainty (expressed as the confidence of variation or the confidence interval) due to random errors and random variations in the procedure. While accuracy is of primary importance, an unacceptably high uncertainty renders the result useless. Apart from the requirements on the quality of the results, the whole analytical procedure must be designed to answer the questions of the analytical task in an economical way (i.e. it should be fit for purpose). Errors can occur in every step of an analysis and negatively influence its accuracy to a degree corresponding to their share of the entire method. In order to reduce such errors, it is of major importance that all steps of an analytical method are documented and that special attention is paid to steps that are particularly critical. Table 2 presents a general scheme of the analytical process for trace metal analysis, where the actual analytical procedure covers steps III–XI. When comparing the estimation of possible errors in each step, it becomes obvious that the most often discussed step, ‘instrumental determination’, is normally the most accurate and precise step of the analytical procedure, while the most critical step, the sampling, often is not even under the control of the analyst. It cannot be overemphasized that the analyst should have all the steps of a method under control since only then can possible problems be recognized, evaluated and, if necessary, remedied.

a + = 2–20%, ++ = 20–50%, +++ = 50–100%, ++++ = 100–300%, +++++ = 300–1000%, ++++++ = production of ‘data cemetery’. QC, quality control.
A number of rules for the conductance and documentation of an analysis, meant to facilitate achievement of such a goal, are generally summarized under the term good laboratory practice (GLP). Further, it is of equal importance to use methods which are fit for the purpose and are well known to the analyst. If such methods are available and validated, their performance has to be controlled throughout the whole duration of the analysis. The installation of a suitable QC program is often a part of the contract or, as many other aspects of environmental analysis, is part of national and international regulations. General guidelines for the installation of such programs are available.\(^{(11)}\) In case of lack of validated methods, effective method development must take place, which has the role of detecting possible sources of errors and eliminating or reducing them to an acceptable level. Normally such method development starts by modifying existing methods rather than starting from scratch.

### 3.2 Sampling and Sample Pretreatment

#### 3.2.1 Sampling

The analytical procedure starts with the removal of a portion from the material to be examined; this is the laboratory sample that subsequently will be analyzed.\(^{(12)}\) During the sampling procedure, care must be taken to ensure that the laboratory sample is representative of the material from which the sample was taken or of the situation which is to be examined. Incorrect sampling renders even the most accurate analysis ad absurdum, a fact often underestimated, since the largest errors take place during sampling and cannot subsequently be corrected. In general, a differentiation can be made between two procedures for representative sampling: (a) random sampling and (b) systematic sampling. Random sampling means the random collection of individual specimens from a total parent population frequently aiming at the determination of an average value (e.g. collection of birch leaves from a birch forest to determine average calcium content at time x). Systematic sampling, on the other hand, mainly refers to problems of changeable values as a function of space and time (e.g. the collection of spruce needles of a certain age or from various levels of a spruce tree to determine the exposure to air pollutants), thereby coupling a specific systematic study to a random sample. Regardless, the following three fundamental sampling rules are valid for both types of sampling:

1. The sample taken from the system should have exactly the same chemical composition as the original material.
2. The probability of being taken as a sample from a total population or total mass of material must be equally great for each individual samples.
3. The greater the variability between individual samples and the greater the number of individuals or the greater the mass of material to be evaluated, the greater are the efforts required for sampling.

Generally, different sources of error prevent the first two fundamental rules from being fulfilled, such as problems with the sampling strategy (place, time, duration and method of sampling), the selection of the apparatus (contamination from the materials used, sorption losses), the execution (sampling, subdividing, homogenization, filtering, preservation) and delivery (transport, identification, protocol). The particular problems depend very much on the type of material or situation to be investigated, and therefore will be discussed later (see section 4).

#### 3.2.2 Sample Preservation

If an analysis is to have any meaning, care must be taken to ensure that the laboratory sample is unadulterated during transportation to and storage at the laboratory while awaiting further sample pretreatment. The preservation of a sample in all of its complexity is impossible and therefore can only be replaced by a ‘freeze’ of selected properties of the sample, such as pH and pE values, as well as the contents of main and trace constituents, matching the needs of the given task. Microbiological activity must be suppressed just as much as analyte concentration changes caused by adsorption losses or contamination. Subdivision of the sample into a number of portions may be necessary if a number of constituents must be determined that require different stabilization. If a number of analytes are in a dynamic equilibrium (e.g. redox equilibrium), such as in speciation analysis, preservation is exceedingly difficult, if not one of the most difficult steps of the whole procedure.\(^{(13–15)}\)

#### 3.2.3 Sample Pretreatment

Since the risk of systematic errors increases with the extent of sample pretreatment, the number of steps and the mass of reagents used during such treatment should be kept to a minimum. Similarly, direct methods are preferred to methods which require extensive preparation such as separation and preconcentration. However, solid samples can generally only be directly analyzed relatively free of problems by GFAAS, so that a digestion is usually required prior to determination. Sample decomposition is prone to three different types of error sources: (a) incomplete dissolution, (b) loss of analytes by volatilization and (c) contamination by the reagents
(acids, etc.). Fusion and dry ashing are the most seriously affected with respect to volatilization losses owing to the higher temperatures employed, but acid digestions are not without problems. All digestion procedures performed in open systems are prone to external contamination, which can be best avoided by operation in closed vessels under pressure.

The risk of errors also increases with decreasing analyte concentration. For those cases in which a low analyte concentration requires separation and preconcentration, all steps should be either carried out under clean working conditions (clean room or clean bench) or performed in a closed system, such as provided by FI manifolds.

### 3.3 Atomic Absorption Analysis and Methods

It has been pointed out already that normally the determination step is the most accurate and precise step of the whole analytical procedure. However, such a general statement can be valid only if the determination step is following a well-developed method, using an appropriate technique and instrumentation that is well calibrated and maintained in good condition. Each of the AAS techniques (e.g. FAAS, GFAAS, HGAAS) has an optimum working range with respect to concentrations, analytes and matrices and should not be used outside this range. AAS is a relative technique in which quantitative determinations are performed by comparison with calibration samples (calibration solutions). Since changes in the instrument parameters, the condition of the instrument, and the conditions of measurement are reflected in the calibration and are thus eliminated (except drift), it is still possible to obtain quantitative results even when the sensitivity is far from optimum. Despite this possibility, working in this manner cannot be recommended since then substantial control of the condition of the instrument is lost. Apart from the fact that the performance characteristics of an analysis are degraded under these conditions, judgment of the analytical data is questionable since significant changes in the sensitivity or noise are indications of malfunctions of the instrument or errors in the method, which may lead to measurement errors.

#### 3.3.1 Instrument Fault Recognition

The absence of instrumental faults is a prerequisite for a meaningful analysis. For this reason a protocol of the performance characteristics of every analysis should be carefully maintained, and any larger deviations from specified values or values in earlier protocols should be a reason to search for the cause.

Frequent causes of a lack of sensitivity in AAS are in general as follows:

1. dilution errors when making up the calibration solutions;
2. wrong or faulty lamp; too high a lamp current;
3. analyte losses in the stock or calibration solutions due to insufficient stabilization or unsuitable containers;
4. incorrect wavelength or too large a slit width;
5. matrix effects due to the use of either the wrong buffer or modifier, or the absence of either.

The following causes can be additionally present in FAAS:

6. wrong flame type or nonoptimized flame stoichiometry;
7. nonoptimized horizontal or vertical burner position;
8. clogged sampling capillary, nebulizer, or burner slot; incorrect aspiration rate;
9. unsuitable inserts in the spray chamber; misaligned impact bead.

Frequent causes of reduced sensitivity in GFAAS (enhanced characteristic mass) are as follows:

10. erroneous sample dispensing;
11. preatomization analyte losses; these can be due to a pyrolysis temperature that is too high or to either an unsuitable or missing modifier;
12. unsuitable (excessive) atomization temperature;
13. erroneous blank value or baseline correction;
14. too high a gas flow rate during atomization or the use of an unsuitable purge gas;
15. too low a heating rate; this can be caused by an unsuitable power supply or poor electrical contact of the graphite tube;
16. too low a magnetic field strength for ZBC (e.g. insufficient voltage at the electromagnet).

Much more seldom than decreased sensitivity is enhanced sensitivity (reduced characteristic mass). This can be traced almost without exception, especially in trace analysis, to accidental introduction of the analyte. If this occurs a systematic search should be made to determine the cause. All analytical results generated under such conditions, and also all corresponding publications, should be regarded with considerable scepticism.

Insufficient precision or excessive noise generally has one of the following causes:

1. low lamp energy; poor quality lamp;
2. wrong lamp current or poor lamp alignment;
3. wrong wavelength or too narrow a slit width;
4. contaminated optical components (windows, lenses, mirrors, etc.);
5. emission noise;
6. poor alignment of the line source and the continuum source for background correction;
7. inhomogeneous sample solution or slurry, the presence of suspended matter in the measurement solution, nugget effect for solids analysis.

For FAAS the following specific causes in addition to those above may be considered:
8. partially clogged nebulizer or burner; defective nebulizer;
9. contaminated spray chamber or inserts (large droplets on the surface are an indication of wetting problems);
10. irregular drain flow from the spray chamber;
11. irregular gas flow (e.g. too low a gas pressure);
12. unsteady flame caused by drafts, strong ventilation system, change of solvent, etc.;
13. an excessively short integration time or insufficient damping.

Specific causes of insufficient precision or excessive noise in GFAAS include the following:
14. irreproducible dispensing of the test sample solution;
15. spattering of the solution caused by either too rapid or incomplete drying;
16. irregular spreading of the measurement solution over the atomization surface (wetting problem);
17. aged graphite tube or contacts;
18. an excessive integration time or incorrect integration window;
19. baseline offset correction (BOC) too short or erroneous.

Finally, drift is often caused by one of the following problems:
1. changes in the radiant intensity of the lamp (or lamps) or of the line profile during the warming-up phase or in the event of a defect; changes in the ratio of the radiant intensities of the line source and the continuum source for background correction;
2. evaporation of the solvent from the measurement solution;
3. for FAAS, warming or cooling of the burner or the formation of encrustations on the burner slot;
4. for FAAS, changes in the rate of aspiration or in the efficiency of nebulization due to physical changes in the sample capillary or the nebulizer;
5. for GFAAS, aging of the graphite tube or the accumulation of residues (e.g. carbon from biological materials).

This list of frequent causes of marked deviations in the most important performance characteristics can only serve as a starting point for troubleshooting. Nevertheless, deviations of this sort are nearly always an indication of a malfunction or an operational error and must therefore be taken seriously. The important performance characteristics such as sensitivity (or characteristic mass or concentration) and the signal-to-noise ratio (S/N) should always be documented with the analytical results so that malfunctions or operational errors can be traced or eliminated. In modern instruments, functions such as monitoring the condition of the instrument and maintaining a protocol are performed automatically with the corresponding algorithms being implemented in the instrument software.

A convenient procedure for monitoring further instrumental functions in GFAAS, in addition to the sensitivity and S/N, has been described by Slavin et al. Using a certified reference material (CRM) (Trace Elements in Water, NIST 1643b), the characteristic masses and the Zeeman factors for chromium, copper and silver are determined without a chemical modifier and under easily reproducible conditions; additionally the lamp energy is recorded. Copper exhibits the greatest loss in sensitivity at the 324.8-nm line when ZBC is applied and is very sensitive to changes in the magnetic field strength. This element can thus serve as an indicator for an insufficiently strong magnetic field. Chromium is a difficult to volatilize element and requires a relatively high heating rate; at the 257.9-nm line its determination is sensitive to emission interferences, which can indicate a poorly aligned graphite tube atomizer. Silver, on the other hand, is not noticeably influenced by the magnetic field strength, the heating rate or the alignment of the graphite tube. If the sensitivity of all three elements is influenced to the same degree, this is an indication of dispensing problems or that the actual temperature deviates markedly from the rated value. If this test is performed at regular intervals, it serves as a powerful tool to document the state of the instrument.

3.3.2 Instrument Optimization

Various strategies have been applied for optimizing the instrument parameters of AAS techniques, such as methods of experimental design, simplex optimization or complete response-surface mapping. The use of such chemometric methods for optimization is useful, since running simple series of experiments changing one parameter at a time may lead to nonoptimum conditions. The situation is further complicated, since different performance characteristics can exhibit varying optima, so that compromise conditions may represent the practical optimum. For example, often it is the case that the conditions for optimum sensitivity are not the same as the
conditions for the best possible tolerance to constituents of the matrix. The required task must therefore be defined before optimization can be undertaken. Frequently, the task is to optimize analytical performance characteristics such as detection capability, precision, working range or tolerance to matrix constituents, but occasionally considerations of economics, such as high sample throughput, minimal manual effort, low sample or reagent consumption or low costs, are more important.

In FAAS we can observe that a burner position or a nebulizer which is optimized for maximum sensitivity can exhibit very low tolerance to matrix constituents. In the case that high sensitivity is not the primary objective, the nebulizer/burner should be optimized for high tolerance against matrix constituents. This is normally done by adjusting the nebulizer and its impact bead (if used) for generating mostly very fine droplets rather than for maximum aerosol density. Also, the observation height for the best sensitivity and the lowest interference effects might be different.

In GFAAS, the stabilizing effect of a modifier (e.g. palladium) can lead to a lower rate of atomization, so that broader signals are obtained than if a modifier were not used. Such signal broadening may lead to a deterioration of the S/N and therefore to a poorer limit of detection (LOD). On the other hand, the linear working range can be extended upward since the limiting absorbance is only reached at higher analyte masses, and the tolerance against concomitants is significantly improved owing to more effective separation during the pyrolysis step and the higher effective atomization temperature.

For samples that do not require the best detection limits achievable by GFAAS, the sample throughput can be enhanced and the analysis costs reduced. This is possible by the reduction of the furnace cycle time. A set of strategies can be combined to achieve fast furnace programs: (a) reduction of the sample volume to the minimum for the required sensitivity allows for (b) shortening of the drying step and (c) if the sample matrix is not complex, for the omission of the pyrolysis step. The drying step can be further shortened if started already during sample dispensing (hot injection). For maximum throughput, the addition of modifiers can be either omitted totally or done in advance directly into the sample cups rather than into the graphite tube.

A different strategy leads to improved detection power. Since the measurement signal of GFAAS is proportional to the analyte mass and not to the concentration, the detection capability can be improved by dispensing larger volumes of the measurement solution. When the upper limit for a single dispensing is reached, which is dependent on the particular design about 40–100 µL, multiple injections each followed by a drying step can be used with modern autosamplers to enhance the total sample mass further. The additional time required for these steps can be reduced by injecting into a preheated graphite tube.

The greatest improvement in sample throughput can be achieved by using simultaneous multielement analysis. However, multielement methods require particular attention to be paid to the optimization of the FAAS or GFAAS operational parameters. The conditions normally chosen for pyrolysis and atomization of various analytes in graphite furnaces differ significantly. This behavior appears to stand in the way of attaining acceptable compromise conditions. However, the selection of compromise conditions is relatively simple, since the most volatile analyte dictates the maximum pyrolysis temperature and the least volatile analyte dictates the minimum atomization temperature. Nevertheless, the use of a transversely heated atomizer with an integrated platform is decisive, since it allows one to apply STPF conditions for both volatile and nonvolatile elements. Losses in sensitivity and selectivity under such compromise conditions are much smaller than assumed when a modern instrument concept is applied. For example, the loss in sensitivity because of an increase in the atomization temperature above the optimum due to increasing diffusional losses is partially compensated for by an increase in the absorption coefficient with increasing temperature. Furthermore, the signal narrows with increasing temperature, improving the LOD since shorter integration times lead to an improvement in the S/N. All in all, only small losses in the detection capability by a factor of 2–3 are expected for multielement determinations, which can be tolerated in many cases.

### 3.3.3 Recognizing and Overcoming Interferences

As a result of a lack of selectivity, the presence of concomitants in the test sample can cause interferences in the determination of the analyte. An interference can influence both the mean value of the analytical results and the attainable precision. A false mean value may lead to measurement errors if it is not eliminated or if it is not taken into consideration in the evaluation report. Measures for the elimination can be instrumental, such as appropriate background correction, or the choice of a suitable calibration technique, such as the analyte addition method, or the use of chemical additives. According to the International Union of Pure and Applied Chemistry (IUPAC), two types of interference can be distinguished, spectral and nonspectral interferences. Spectral interferences are due to the incomplete isolation of the radiation absorbed by the analyte from other absorption or radiation sources. Nonspectral interferences directly affect the number of free analyte atoms in the absorption volume and can be further classified according to the place or time of their occurrence.
3.3.3.1 Spectral Interferences  Since AA spectra are much simpler than those of optical emission spectrometry (OES), spectral interferences are encountered far less frequently than in OES. The following cases can be distinguished:

1. direct overlap of the analytical line with an absorption line of another element;
2. absorption of the radiation of the analytical line by gaseous molecules;
3. absorption by concomitants of other radiation from the radiation source (or sources) that is not separated by the monochromator;
4. radiation scattering caused by particles in the absorption volume;
5. thermal emission of concomitants in the bandwidth of the monochromator.

While the thermal emission of concomitants is generally corrected for in AAS by modulating the primary radiation source, the light still reaches the detector. In the case that the amount of light from this interfering source is significant with respect to the modulated light from the primary source, increased noise is detected, lowering the attainable precision.

Only a limited number of direct overlaps occur in AAS, and of the 38 cases reported\(^2\) only 10 are related to primary analytical lines. In most cases the interfering element must be present in a large excess to cause false measurement, which has not been reported in environmental analysis.

Spectral interferences of type 1 and 3 can be observed more often and also have been reported for environmental analysis. When a continuum source is used for background correction, any concomitant that exhibits an analytical line within the bandwidth of the monochromator can absorb radiation from the continuum source to a degree corresponding to its concentration. This supposed background absorption is then falsely subtracted from the AA, leading to overcompensation and thus to a measurement error. In order to absorb significant amounts of the radiation from the deuterium source, the interferent must be present in high concentrations. Normally this type of interference can be observed in the determination of trace elements in metallurgical samples such as alloys. However, a few cases have also been reported for environmental samples, where the matrix element iron interferes with the determination of Pb 217.0 nm and Cd 228.8 nm\(^{23}\) and Se 196.0 nm and Sb 217.6 nm\(^{24}\) and aluminum interferes with the determination of As 193.7 nm\(^{24,25}\) and Sb 217.6 nm.\(^{24}\) Molecular absorption also can lead to interference, either directly by overlapping with the analytical line (type 2) or by absorbing radiation from the background correction channel (type 3). Particularly cumbersome are the interferences from P–O for the determination of arsenic, selenium and tellurium and from S–O for the determination of selenium.

Generally, problems arising from background absorption (interference type 3/4) are more frequent with GFAAS than with FAAS.\(^{26}\) In flames, background absorption is rarely significant at wavelengths higher than about 240 nm, rarely exceeding 0.05 absorbance. In furnace analysis, background absorption can be significant at wavelengths up to 500 nm, exceeding signal levels of 2 absorbance units. Type 4 spectral interferences (light scattering) is caused by the condensation of the sample matrix (or the modifier!), by forming a smoke or mist. This event occurs when a huge amount of volatilized matrix reaches cooler regions in the absorption volume, caused by temperature gradients inside the atomizer.

The prerequisite to counter such interferences is to recognize them. Spectral interferences can be detected by changing to another alternative analytical line, by changing the slit width of the monochromator and by measuring a matrix blank solution that is identical to the test solution but does not contain the analyte. In GFAAS, careful inspection of the time-resolved absorption signal may give indications of spectral interferences, for example, when the analyte signal falls below the baseline or when the analyte signals shows minima coinciding with maxima in the background channel. To counter such interference problems, there are some complementary measures available to the analyst:

1. selection of the appropriate background correction;
2. optimization of the temperature programming;
3. use of chemical modifiers.

Interferences of type 2 and 3 can in general be compensated by ZBC with the exception of molecules showing a Zeeman effect.\(^{27}\) Such behavior has been reported for the molecular species N–O in the determination of Zn 213.9 nm\(^{28}\) and Se 196.0 nm\(^{29}\) and P–O in the determination of Ag 328.1 nm, Cd 326.1 nm, Fe 248.3 nm, Hg 253.6 nm and Pd 244.8 nm.\(^{30,31}\) For such cases the optimization of the method is the only measure to avoid these interferences. The goal of method optimization is either to avoid the interferent species (do not use phosphate modifier, phosphoric acid, in digestions or extractions) or to separate the analyte and the interferent species by optimizing the thermal programming of the atomizer and the use of appropriate modifiers.

3.3.3.2 Nonspectral Interferences  Nonspectral interferences are those which have an influence on the number of analyte atoms in the absorption volume. In the case where the mechanism of the interference is known, the interferent can be classified by naming the place where it

ENVIRONMENT: WATER AND WASTE

1. check for contamination;
2. determination of the precision within a series and between series;
3. determination of the LOD and limit of quantification (LOQ);
4. determination of the linear working range;
5. check for possible interferences;
6. comparison of the analytical results with those from alternative methods;
7. comparative analyses with other experienced laboratories;
8. analysis of CRMs closely matching the composition of the target sample.

Since a contract laboratory can only select methods that have been adequately characterized, in principle it cannot accept chance analytical tasks.

3.3.5 Measurement, Calibration, Evaluation

The material obtained after suitable treatment or preparation of the laboratory sample is the test sample (or, if only analytical chemistry is involved, the analytical sample). A test (or analytical) portion is removed from this for analysis. If the sample is a solid material, it may be analyzed directly by solid sampling GFAAS. In most cases it is transferred into a test sample solution, by performing a digestion, extraction or dissolution. The test sample solution can be used directly or after further treatment steps, such as dilution, addition of buffers or modifiers, and so on, for the measurement. After having sorted out all the possible error sources during method development and instrument maintenance, only a few errors sources remain that may influence the final measurement. The measurement solution actually used for the measurement by AAS must be stable for the duration of the analysis. This is especially important if an autosampler with numerous sample cups is used, since the measurement solutions can stand for several hours before being analyzed. While solvent extracts with volatile solvents or complexes with unstable metal chelates are particularly critical, even aqueous solutions become more concentrated with time; this effect becomes greater the smaller is the volume of the sample container. The evaporation rate from 2-mL standard GFAAS autosampler cups at normal room temperature is about 35 \( \mu \text{L h}^{-1} \) and can be reduced to about 10 \( \mu \text{L h}^{-1} \) when the autosampler is covered, and additional containers filled with water for humidification are placed below the cover.\(^{(16)}\)

Another significant source of errors for the instrumental determination is the calibration.\(^{(32)}\) Errors occur mainly during the preparation of calibration solutions by dilution of stock solutions. The dilution error increases with both the number of dilutions and the ratio of the dilution step.\(^{(33)}\) In order to reduce such errors, only calibrated volumetric devices of quality class A should be used or, better, the dilutions should be performed gravimetrically;
Increasing interest is also reflected in the launch of the systems which are currently being implemented. The number of QA guidelines for environmental analysis was a growing feature of the 1990s, as illustrated by the number of QA guidelines and systems which are currently being implemented. The increasing interest is also reflected in the launch of the journal Accreditation and Quality Assurance in 1996.

3.4 Quality Assurance

The accuracy of a determination depends not only on the selection of a suitable procedure, but also on the stability of the performance characteristics of that procedure. In principle, two different strategies are applied to verify that both goals are met. QC is the mechanism of verifying the absence of errors, while quality assessment is the mechanism of verifying that the system is operating within known and acceptable limits. (35) Quality assurance (QA) for environmental analysis was a growing feature of the 1990s, as illustrated by the number of QA guidelines and systems which are currently being implemented. The increasing interest is also reflected in the launch of the journal Accreditation and Quality Assurance in 1996.

3.4.1 Internal Laboratory Operations

The quality of laboratory operations, in the most general sense, is measured by the dedication of higher management to emphasizing quality in a delicate balance with the ever-present demands of productivity. QC always requires a high level of effort and must therefore be accommodated to the DQO (i.e. the higher the requirements on the accuracy of a method, the greater is the effort required for QC). Nevertheless, higher costs for QC can be justified when costs in other areas are reduced, such as those caused by repeated measurements or by false results.

The first requirement for implementing a QA program is the organization of events in the laboratory following certain rules that are generally summarized as GLP and good analytical practice (GAP). GLP provides guidance in the organization of laboratory events and for the conditions under which laboratory investigations are planned, conducted and assessed. By maintaining a protocol and issuing a report of the investigation, the aim of GLP is to make procedures in the laboratory so transparent that they can be verified by third parties (e.g. regulatory authorities, clients). The scope of these rules are laid down in the chemical legislation in force in most industrial nations. The installation of such rules is most often part of the contract between the client and the laboratory. A detailed discussion on this topic is beyond the scope of this article and the interested reader is therefore referred to introductory monographs. (36) Maintaining all the rules of GLP is both expensive and requires a considerable increase in personnel. Some typical violations of GLP rules are as follows:

1. balances remaining uncalibrated;
2. failure in recertifying mechanical pipets;
3. use of pH buffers of unknown age or origin;
4. use of unsuitable purity standards;
5. application of software beyond its purpose.

On the other hand, GLP alone cannot guarantee the trueness and quality of analytical data. The final responsibility for QA still remains with the analyst. QC and quality assessment programs must be implemented and the rules of GAP must be followed in a laboratory to reach the DQO. The rules of GAP include the following:

1. performing the analysis with an adequate number of adequately trained staff;
2. the use of validated methods;
3. analytical instruments that are calibrated and maintained in good condition;
4. the use of CRMs for calibration;
5. an effective internal QA program.

As far as possible, effective QC should be incorporated directly into the analytical program. Analytical results cannot first be generated and then deliberations subsequently made about their quality. Typically, the more complex the sample, the greater the effort the laboratory should make with respect to QC. Depending on the DQO, the QC program must be designed either to maximize the probability of error recognition or to minimize the probability of a false warning. By trapping and excluding error sources such as drift, the QC program can lead to an improvement in the method performance.

In order to be effective, at least the following procedures should be part of the internal quality assessment:

1. characterization and optimization of the precision and accuracy of the calibration function; (37)
2. characterization of the blank values;
3. characterization of the instrumental repeatability (precision on replicates);
4. characterization of the method repeatability (precision on duplicate samples);
5. characterization of the method performance by analyzing a control sample of known analyte content (recovery);
6. characterization of the accuracy of the method by analyzing a CRM (recovery).

To assure that the method is under statistical control, the results of such performance checks are documented in the form of control charts. Control charts serve multiple functions, including:

1. recognition of drift or malfunctions;
2. to uncover errors in sampling or sample preparation;
3. to decide, whether the analysis is fit for purpose;
4. to support the analyst with respect to his/her clients by assuring his/her results.

### 3.4.2 External Quality Control

Outside evaluation of the laboratory provides an opportunity for the laboratory to view quality from another perspective. The GAP rules include the following external QC:

1. regular participation in interlaboratory (‘round-robin’) trials;
2. quality assessment by an independent QA unit;
3. accreditation or other certification of the laboratory by regulatory authorities.

Regular interlaboratory trials are organized by several national and international quality programs, sending performance evaluation samples to the participants before an audit or as part of ongoing performance checks. An on-site audit by a third party group can be very effective in reviewing the installed quality programs.

### 4 ENVIRONMENTAL REGULATIONS AND METHODS

Environmental studies cover a broad range of disciplines, for example, analytical chemistry, geology and biology, and include several aims such as monitoring (routine analysis), research (studies of environmental pathways) and modeling. In many cases chemical analyses are the basis of these studies. Environmental analysis traditionally is divided into the analysis of water, soils and the atmosphere. Such ‘classical’ division cannot be strictly followed here in view of the multitude of different environmental samples originating from the different compartments of the ‘environment’ and the mutual interactions that can be expected between them (see Figure 3).

Nearly all types of sample materials can become the target of environmental analysis, at least when the material is disposed of as waste. In order to assign the most widely varying materials into suitable categories, three categories were chosen. The categories are based on the analytical methods used for their analysis, rather than the environmental compartment from which they are taken; the categories are (a) water samples, (b) solid materials of mainly mineral phases and (c) biological materials.

A particular characteristic of environmental analysis is that most aspects of the analysis, i.e. the frequency of the analyses, the strategy and methods of sampling, the pretreatment and instrumental determination, the QC of analytical results and the data presentation) are governed to a large extent in the finest detail by laws, regulations and guidelines. An overview of prescribed analytical methods and of international and German standards was given by Hein and Kunze. Since the analyst must procure and follow the original method exactly, in order to be compliant with these rules, details of such methods will not be presented here. Instead, information will be given that will point to the most important work.

Introductory information on environmental analysis is available in the form of monographs and review articles. Publications on the determination of individual elements in environmental samples are also available, for instance, for aluminum, arsenic, cadmium, chromium, cobalt, copper, lead, manganese, mercury, molybdenum, nickel, platinum, selenium, tellurium, thallium, tin, vanadium, and zinc. Regular reviews of environmental analytical chemistry appear annually in the *Journal of Analytical Atomic Spectrometry* and every second year in *Analytical Chemistry*. The application of AAS in...
environmental analysis has been recently reviewed by Sturgeon.\textsuperscript{(104)}

4.1 Water Analysis

Although the compound H\textsubscript{2}O is clearly defined for the chemist, the matrix ‘water’ offers an unbelievable multitude of forms for the analyst, reflected in the number of methods for its analysis. Water samples can be classified by legislators, analysts or users by the degree of its anthropogenic contamination (natural waters, processed water, polluted water, wastewater), by its salinity (fresh water, briny water, seawater), by its environmental compartment (atmospheric precipitation, surface water, groundwater, glacial ice) or by its intended use (drinking water, cooling water, bathing water, process water). Correspondingly, the palette ranges from highly pure waters to waters containing extremely high contents of impurities, with respect to both the analyte concentration and the matrix content. The parameters analyte concentration, total salt concentration and organic content are decisive for the procedure and the selection of the analytical technique.

Even though most natural waters contain over 99.9\% of H\textsubscript{2}O, accurate determination of elements in this simple matrix is frequently not as straightforward as would first appear. Most unpolluted natural waters contain less than 10\(\mu\text{g} \cdot \text{L}^{-1}\) of the commonly determined toxic metals and it is easy to obtain significantly biased results when measuring such low concentrations. The problem is obvious from the history of published concentrations of trace elements in seawater, which had decreased by around an order of magnitude within a decade. This is primarily due to (a) the improvements in the control of contamination during sampling, storage and analysis, and (b) the improved separation techniques and advances in the development of the instrumentation.\textsuperscript{(106)} Therefore, the majority of data on the determination of the base concentrations of metals in seawater published before 1986 is practically worthless.\textsuperscript{(107)} The same is probably true for other non-polluted waters and rainwater. Toxic metal levels in sewage and effluents are normally significantly higher than those of natural waters. However, interlaboratory comparison studies have demonstrated that inaccurate results at these higher concentrations can still occur unless meticulous attention to detail is observed in this case particularly to the control of interferences.

For an overview on water analysis, special monographs\textsuperscript{(108–112)} and review articles\textsuperscript{(113)} on this topic or more specific publications on seawater analysis\textsuperscript{(114–117)} should be consulted. Review articles on the determination of trace elements in water are available for aluminum\textsuperscript{(118–120)} antimony\textsuperscript{(121,122)} iron\textsuperscript{(123)} and mercury.\textsuperscript{(124)} The journals Water Research and Vom Wasser (in German) deal exclusively with this subject.

4.1.1 Water Analysis and Legislation

As mentioned previously, environmental analysis is regulated to a large extent by national and international laws and regulations. Since water is a prerequisite for life, it is of primary concern. The different types of water meant to be consumed or used by humans or being discharged into the environment are extensively regulated and controlled. It is beyond the scope of this article to discuss such regulations in detail. However, some limits for a range of elements in treated (potable) water are given in Table 3 in order to discuss the applicability of AAS for the control of water quality.

In order to monitor for these elements at concentrations close to the limits set by regulations and to determine compliance, the LOD of the analytical technique should ideally be at least 10 times lower than the actual limit. By comparing the achievable LODs of different AAS techniques with these control limits, it is clear that FAAS can only be used to monitor directly seven of the 16 elements listed in Table 3.

4.1.2 Sampling and Sample Conservation

Appropriate sampling and subsampling techniques are a crucial prerequisite of the generation of meaningful results. Appropriate sampling and subsampling techniques are a crucial prerequisite of the generation of meaningful results.

Table 3 Some international standards for treated potable waters (all concentrations in \(\mu\text{g} \cdot \text{L}^{-1}\))

environmental data. The technique of sampling has to be selected in accordance with the requirements determined by the type of water that is to be sampled, such as piped water (drinking and industrial waters), springs and wells, groundwater (bore holes, seepage waters), flowing surface waters (canals, creeks, rivers, streams), still surface waters (ponds, lakes, barrages), marine waters and precipitation. The majority of still and flowing waters exhibit substantial variations in their element concentrations over time and in their spatial distribution. It is therefore relatively difficult to take a ‘representative’ sample. The required task must therefore clearly be established before sampling is undertaken. The simplest case is to take random samples, for example, at an outflow location at a given time. However, sampling of this type is only meaningful when the place and time of sampling are clearly defined, based on prior detailed information, and refer to a special situation. Much better information can be obtained for one or several analytes by determining the change in concentration with time, either continuously or at regular time intervals. For example, such sampling could be meaningful for the inflows and outflows of a sewage treatment plant. The degree of information can be further enhanced by a network of sampling points (e.g. along the length of a river or over the depth profile of a lake), and changes at each sampling point over the short term (days) or over the long term (months, years) are monitored. Multivariate statistical procedures can aid in the interpretation of such complex data.\textsuperscript{125}

Sampling strategies are described in numerous national and international standards,\textsuperscript{49} some of which are given in Table 4, and also in a number of review articles.\textsuperscript{106,113,126}

The collection of wet precipitation (rain, snow, cloud aerosols, etc.) is especially challenging,\textsuperscript{127} particularly when the wet precipitate must be kept separate from the dry precipitate. For this purpose, rainwater collectors have been designed using a device that covers the collector during dry periods and opens only at the onset of rain\textsuperscript{128–131} or by changing the exposed collection funnel by moving the cover at that moment.\textsuperscript{132} Materials for such precipitation collectors have to be selected with care, since substantial errors can occur owing to adsorption on the walls of the collection funnel and sample container.\textsuperscript{133} Collection time is also important, especially if an appropriate preservative has not been added.\textsuperscript{134}

Also problematic is the collection of seawater samples from different depths or from the water surface, which contains high concentrations of surface-active compounds (biofilm). The ship itself and all the equipment used for sampling (winches, wires, bottom weights, samplers and messengers) are potential sources of contamination either due to their material or by their action (mixing different layers). These problems are discussed in more detail in review papers on seawater sampling.\textsuperscript{106,135}

The sample pretreatment following the sampling of water samples depends on whether the total concentration or the concentration of dissolved analyte should be determined. In the first case, the water sample may have to be digested depending on its properties and the selected analytical technique. In the second case, the water sample is filtered after sampling, usually through a membrane filter of pore size 0.45 µm. Even such a simple task might not be without problems. Dissolved analytes might be lost during filtration owing to adsorption on the filter material or apparatus,\textsuperscript{136} or the sample might become contaminated during filtration.\textsuperscript{137} Various parts of colloidal forms of the analytes might pass through the filter, depending on the state of the filter with respect to loading with solid material.\textsuperscript{138–140} For these reasons, those variations introduced during sampling of water are

</table>
often significantly higher than the instrumental variation of the measurement.\(^{141}\) Immediately following filtration, or sampling if the sample is not filtered, the sample must be stabilized, usually through the addition of 10 mL of nitric acid per liter of water sample. The requirements for preservation are different for the different water samples (e.g. high salinity acts in a stabilizing manner), and also depend very much on the elements to be determined. In general, the pH value must be \(<1.5\) in order to minimize the risk of analyte concentration changes due to precipitation or wall reactions. Different procedures may be required if individual element species are to be determined (see section 4.1.5). If the sample has been filtered, it may be of interest to examine the residue separately, following a method often very similar to those used for the analysis of sludges or sediments (see section 4.2).

Preconcentration at the site of sampling has been proposed as a strategy for sample preservation;\(^{142}\) the claimed advantages are (a) large volumes of sample do not need to be transported, (b) concentrated samples are more stable and (c) the risk of contamination during transport and storage is reduced. The disadvantages are that preconcentration is a selective procedure, including only (a) selected elements, (b) mostly ionic species and often (c) only one oxidation state of the analyte, unless a comprehensive sample preparation procedure is performed at the sampling site. If interferences occur during preconcentration, it is very difficult to recognize them subsequently, since the original sample is no longer available. This strategy has not received wide acceptance and has only been used for special cases such as the determination of gold\(^{143}\) and the determination of species of chromium\(^{144}\) and mercury.\(^{145}\)

Samples should be analyzed soon after sampling, especially when species determination is desired. Stabilized samples should be kept in appropriate containers, whereby the most suitable material depends on the target analytes and the concentration levels [details can be found in an overview published by Sturgeon and Berman\(^{126}\)]. The best materials for the storage of samples with very low concentrations of analytes are fluoropolymers with a very smooth surface,\(^{146}\) such as perfluoroalkoxy (PFA) [polyfluoroethylene (Teflon\(^{8}\)PFA)]\(^{147–149}\) or polished polytetrafluoroethylene (PTFE) (Teflon\(^{8}\))\(^{150}\) with the exception of mercury, for which glass is the best material.

### 4.1.3 Methods for Flame Atomic Absorption Spectrometry

According to most official methods for water analysis by FAAS, a digestion can be omitted if the analyte can be completely detected without such pretreatment. Normally, this is the case for filtered and stabilized water samples and often even for unfiltered water samples, provided that they do not contain large amounts of suspended matter that could block the sample introduction system or cannot be fully atomized in the flame. However, the direct analysis of water samples by FAAS is limited by its lack in sensitivity. Apart from the main elements sodium, potassium, calcium and magnesium, and under given conditions strontium, none of the trace elements can be determined in unpolluted surface waters, rainwater and seawater directly by FAAS. If the task is to monitor given limiting values, such as in the drinking water regulations or other corresponding international guidelines (see Table 3), then it is also possible in some cases to control for barium, copper, iron, manganese and zinc, and under given conditions for cobalt and chromium. For the analysis of some wastewaters, seepage waters or more strongly polluted surface waters in general, it is also often possible to determine elements such as cadmium, lithium, nickel and lead satisfactorily by FAAS. However, for such types of sample, a digestion is often indispensable.

By far the most often used digestion procedure for the determination of heavy metals in polluted waters by FAAS is digestion in nitric acid–hydrogen peroxide. Nitric acid and hydrogen peroxide are added to the water sample in a beaker and the volume is reduced to a wet residue, if required under repeated addition of hydrogen peroxide. The residue is taken up in nitric acid and water and the digestate is analyzed by FAAS.

In order to avoid potential interferences, to which especially the analysis of strongly polluted waters might be exposed, the following points should be particularly observed:

1. **Background correction** should be used for all determinations at wavelengths \(<350\) nm.
2. The nitrous oxide–acetylene flame should be used for the determination of chromium and is also strongly recommended for the determination of iron and manganese in water samples with complex matrices (e.g. wastewater), even if the sensitivity with this flame is poorer than that with the air–acetylene flame.
3. The addition of at least 2 g L\(^{-1}\) La as the chloride is required if calcium and magnesium are determined with the air–acetylene flame.
4. The addition of 1 g L\(^{-1}\) Cs as an ionization buffer is recommended for all determinations with the nitrous oxide–acetylene flame and also for the determination of sodium and potassium with the air–acetylene flame.
5. The operating conditions should be optimized for minimum interferences rather than for maximum sensitivity, particularly for strongly polluted waters.
If the sensitivity is then inadequate, a more sensitive AAS technique should be chosen (e.g. GFAAS). Before GFAAS was introduced as a more sensitive technique in AAS, preconcentration by solvent extraction in combination with FAAS was used for the determination of trace elements in fresh waters. In this case complete digestion of the sample is essential. Nowadays, such methods are seldomly used routinely even though large numbers of these have been and continue to be published. The arguments against such methods are numerous (e.g. lack of sample throughput, involvement of too much manual work, contamination problems and the presence of interferences are only some examples). As a general rule, direct determination by other more sensitive techniques is generally preferred. A possible exception is on-line preconcentration,\(^{(151)}\) for example, by sorption on packed microcolumns,\(^{(152–156)}\) and this aspect is discussed in more detail together with GFAAS.

Table 5 lists methods for the analysis of water samples by FAAS.

### 4.1.4 Methods for Graphite Furnace Atomic Absorption Spectrometry

With a sensitivity of about 2–3 orders of magnitude higher than that for FAAS, GFAAS offers the best prerequisites for the direct determination of a large number of trace elements in water. Also, digestion is not required for the majority of water samples, since in situ pretreatment such as oxygen ashing can be made part of the GFAAS heating procedure. Even water samples with a high content of suspended particles, which call for a homogenization directly prior to dispensing, can be directly analyzed with the aid of a slurry sampler.\(^{(170)}\) The quantities of reagents and external

</table>
pretreatment steps can be thus reduced to a minimum for GFAAS, which is a prerequisite for accurate results in the extreme trace range. This reduction of sample pretreatment compensates for the often-cited disadvantage of GFAAS that the measurement time is relatively long and the sample throughput is low, which can be largely overcome by the use of state-of-the-art instrumentation, providing fully automated sequential or even simultaneous multielement analysis.

Another often cited disadvantage of GFAAS is its susceptibility to interferences. The relevance of such interferences, especially those reported in the early history of the development of the GFAAS methodology, has been greatly reduced with the introduction of the STPF concept by Manning and Slavin in 1983. These and later authors showed that numerous trace elements in surface waters could be determined free of interferences against matrix-free calibration solutions by applying the STPF concept, including platform atomization, the use of matrix modification and ZBC. Nowadays, many standard methods are based on a direct determination, such as EPA 200.9 for the determination of Ag, Al, As, Be, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Sb, Se, Sn and Tl and EPA 7010 for the determination of Ag, As, Ba, Be, Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb, Se, Tl, V and Zn. Similar methods exist in Europe for Ag (DIN 38 406-E18), Cd (ISO 5961-1995, DIN 38 406-E19), Co (DIN 38 406-E24), Cr (ISO 9174-1990, DIN 38 406-E10), Ni (DIN 38 406-E11), Pb (DIN 38 406-E6), Se (DIN 38 405-E23), Tl (DIN 38 406-E21) and Zn (DIN 38 405-E8), and STPF conditions are recommended, even if they are not directly prescribed. Publications of direct determinations of trace elements in natural water samples are very numerous, and only selected papers are given in Table 6.

The probability of interferences increases with the complexity of the sample matrix and the requirements for low detection limits. Strongly polluted water samples usually contain a higher analyte content and therefore allow for substantial dilution, which greatly reduces interference effects during analysis by GFAAS. Mineral and therapeutic waters can nevertheless cause considerable analytical problems on occasion if they have a high matrix content, e.g. of sulfur compounds, or when the analyte concentration is very low. Samples of such complexity require very careful method development, method optimization, validation and QC.

If the sensitivity of GFAAS is inadequate for the direct determination of trace elements in very pure water, the sensitivity can be markedly increased by using multiple injections or by carefully reducing the sample volume by evaporation. Nevertheless, while such procedures can easily be used for waters with low concentrations of inorganic or organic concomitants, more problems are expected when applied for wastewater, high-salt mineral water or seawater, so that the application for such samples is limited to cases where the analyte can be easily separated from the large amounts of matrix by thermal pretreatment. Often, separation and preconcentration steps cannot be avoided for such complex samples.

The trace element concentrations in unpolluted seawater are in the lower micrograms to nanograms per liter range. From a comparison of the best published LOD for GFAAS with the trace element concentrations of two unpolluted seawater samples of different origins, one could conclude that it should be possible to determine a number of trace elements directly by GFAAS (see Table 7). However, an additional difficulty with seawater samples is the total salt concentration of 35 g L\(^{-1}\) on average, which can lead to spectral and nonspectral interferences.

State-of-the-art systems providing high-performance ZBC together with STPF conditions are able to overcome these problems in some cases, as is demonstrated by selected publications on the direct determination of trace elements in seawater compiled in Table 8. However, scrupulous optimization of the instrumentation and methods is necessary in order to reduce interferences to an acceptable level and to achieve the necessary S/N level. For this purpose the following points should be taken into consideration:

1. The STPF concept must be applied consistently to minimize spectral and nonspectral interferences. A THGA with integrated platform provides the best results.
2. As much of the chloride matrix as possible must be removed prior to atomization. The addition of ammonium nitrate or nitric acid as a modifier aids in vaporizing the chloride as NH\(_4\)Cl or HCl.
3. The thermal stability of volatile elements should be enhanced by the addition of modifiers (e.g. Pd) and/or the addition of hydrogen to the purge gas during the pyrolysis.
4. Since high background attenuation is to be expected, even when the matrix is largely removed, the application of ZBC is recommended.
5. A polarizer is not required for the longitudinal configuration of the magnet for ZBC. This configuration thus provides a better S/N than other configurations.

Even then, only a limited number of elements can be determined directly in seawater. For the others, as with the analysis of fresh water, preconcentration is indispensable. Great care is required to avoid errors at such a low concentration range < 1 µg L\(^{-1}\) owing

*a* PIXE, particle-induced X-ray emission; ASV, anodic stripping voltammetry.

To contamination or analyte losses, and the following guidelines should be considered:

1. The number of necessary steps in the procedure, the number of containers, funnels, etc. and the mass of added reagents should be kept to a minimum.

2. All containers should be used exclusively for trace analysis and must be cleaned thoroughly prior to use, preferably by fuming out with nitric acid or in the case of very clean PFA by leaching with dilute aqueous solutions of H₂O₂, ammonia and triethanolamine, which reveals comparable cleaning effects for this material.\(^{(243)}\)

3. All reagents must be of the highest purity. If necessary, they must be further purified, e.g. by subboiling distillation.

4. All procedures should be performed in a clean room, clean work-bench or at least in a dust-free environment in a closed system, to minimize contamination from the laboratory atmosphere.

5. Polymer containers, funnels, etc. become aged with usage, developing active sites on the surface,²¹⁴ being able to exchange ions,²²⁴ and therefore must be exchanged regularly for new ones.

6. On-line procedures in closed systems²⁵¹ are superior to all manual batch procedures owing to the significantly lower risk of contamination and to their much better repeatability and reproducibility.

For preconcentration, different techniques, such as liquid—liquid extraction,²⁴⁵ coprecipitation,²⁴⁷ ion exchange and solid sorbent extraction²⁴⁸ electrodeposition,²⁴⁹ might be considered, but some specialities have to be taken into account with respect to their combination with AAS techniques.²⁵⁰ For the combination of solvent extraction techniques with GFAAS, the following facts should be considered:

1. Although organic solvents have the advantage of enhancing the sensitivity in FAAS, they tend to be a disadvantage in GFAAS since they often wet graphite and can spread uncontrollably.²⁵¹

2. Organic solvents containing halogens are a potential source of gas-phase interferences.²⁵²,²⁵³

3. Organic solvents tend to evaporate from the sample cups, and some of the complexes extracted are unstable, calling for a back extraction into aqueous media.

The most often used methods for solvent extraction of trace metals from seawater are based on the use of dithiocarbamates as chelating agents.²⁵⁴ A standard procedure is based on the use of equal amounts of ammonium pyrrolidine dithiocarbamate (APDC) and diethylammonium diethyldithiocarbamate (DDDC) at pH 4–5, which is adjusted with an acetate buffer.²¹⁸ Freon TF (1,1,2-trichloro-1,2,2-trifluoroethane) is chosen as an organic solvent because of its low toxicity, its

</table>
very low solubility in water (0.017% m/m at 21 °C), its quick separation from the aqueous phase and its low metal blank even at technical-grade quality. Alternatively, the metal chelates may also be extracted into chloroform. In order to overcome stability problems of the extract, the analytes are transferred back into acidic aqueous solution. This can be performed by either back extraction into dilute nitric acid or by smooth evaporation of the solvent and acidic redissolution of the metals. Very high preconcentration factors of up to 6000 have been reported by such a combination of extraction and back extraction.

Coprecipitation as a method for preconcentration has also often been combined with GFAAS determination, having its own advantages and disadvantages:

1. Carriers for coprecipitation are potential source of contamination, since they are added in excess.
2. Coprecipitation carriers that can be easily vaporized or decomposed during the pyrolysis step are particularly suitable; these include elements such as indium, mercury, selenium and tellurium and organic reagents.
3. Coprecipitation carriers, that act as modifiers, such as magnesium, nickel and palladium can also be advantageous.
4. The use of hydroxy precipitates is preferred to that of sulfides, which tend to create interference effects.
5. An interesting aspect of preconcentration by coprecipitation in combination with GFAAS is the direct analysis of the precipitate as the solid or a slurry.

The use of ion exchangers and solid sorbents for preconcentration has found particular attention recently:

1. Column-based methods are particularly suitable for automation and even on-line methods are possible.
2. The sorbent can be used repeatedly, and often the amount of added reagent is reduced compared with other preconcentration methods.
3. Closed systems in general are easier to control for contamination. However, some ion-exchange resins and solid sorbent materials produce persistent and irreproducible blanks, owing to contamination of the polymeric material during its production.
4. Organically bound metals might be lost during preconcentration, especially when using ion-exchange or solid-sorbent extraction, calling for a digestion procedure prior to preconcentration [e.g. ultraviolet (UV) photolysis].

Since ion exchangers seldom have the desired selectivity for the trace analytes, other solid-sorbent techniques have been developed, based on the use of more selective functional groups. At least two different approaches can be differentiated:

1. A chelating compound is added to the sample or preloaded on to the column. The column is often a hydrophobic (reversed-phase) material, which retains the chelating agent or the metal–chelate complex by sorption. Often used sorbents for this approach are silica C-18, activated carbon and macroporous resins such as Amberlite XAD-4.

2. A functional group is permanently bound to the base material by a coupling reaction during the synthesis of the sorbent. Typical sorbents of this type are Chelex-100, Muromac A-1 and 8-hydroxyquinoline bound to controlled-pore glass (CPG) or silica.

A standard method using macroporous iminodiacetate chelating resin is available and can be used for the preconcentration of Cd, Co, Cu, Pb and Ni. Further details on solid-sorbent extraction techniques can be found in some review articles.

On-line procedures especially for sorbent extraction with GFAAS detection, mostly based on FI, have been increasingly applied, using the same or similar sorbents as for off-line techniques. These on-line procedures offer a number of advantages:

1. The analysis time may be substantially reduced, since an equilibrium state is not needed.
2. There is a much lower risk of contamination since preconcentration and elution are performed in a closed flow system. Only inert materials and small surface areas are used, and the reagents can be purified on-line.
3. Since reactions such as acidification, complexing and sorption take place on-line and can follow each other in rapid sequence in a reproducible way, it is also possible to work with unstable complexes or intermediate products.
4. All processes can be easily automated.

On-line preconcentration procedures have made possible the determination of trace elements in the lower nanograms per liter range in seawater on a more or less routine basis. Commercial instrumentation including the necessary software, allowing for the coupling between FI and GFAAS, is available. Proposed methods are based on the use of the reversed-phase sorption of chelate complexes with
dithiocarbamates\textsuperscript{(288–290)} or dithiophosphates,\textsuperscript{(291)} immobilized 8-hydroxyquinoline\textsuperscript{(292)} or Muromac A-1.\textsuperscript{(293)} An overview of such techniques was given by Fang and Tao\textsuperscript{(294)} and progress has been reviewed by Fang.\textsuperscript{(294)}

\textbf{4.1.5 Methods for Speciation Analysis}

Speciation analysis is an area which has found increasing interest in the 1990s. Element species can be distinguished by their oxidation state (redox species), by their molecular form (organometallic compound), by coordination (complex), by the phase in which the analyte exists (dissolved, colloidal, suspended) or by its solubility (leachability, bioavailability). In this broad sense, the analysis of filtered water samples is in principle already a form of speciation analysis. This physical separation can be refined to a fractionation of particulate and colloidal species via multistage filtration and ultrafiltration\textsuperscript{(295)} and can be automated by means of FI-type manifolds\textsuperscript{(296)} or field-flow fractionation. Methods used for such a type of speciation for water samples have been reviewed by De Mora and Harrison.\textsuperscript{(297)}

Considerably more detailed deliberations on the term ‘species in aquatic systems’ can be found in the monographs by Batley,\textsuperscript{(298)} Krull,\textsuperscript{(299)} Ure and Davidson\textsuperscript{(300)} and Tessier and Turner.\textsuperscript{(301)} In this section, however, the focus is on chemical species such as redox species and organometallic compounds. Very few direct methods exist for the determination of such species. More often, separation techniques have to be combined with suitable detection techniques. As far as speciation analysis is concerned, the FAAS technique lacks sensitivity, whereas the more sensitive ETAAS is not particularly suitable for detection in gas chromatography (GC), high-performance liquid chromatography (HPLC), and other chromatographic techniques most often used for the separation of trace element species. Therefore, AAS techniques can be ranked in the following decreasing order of their potential for speciation: HGAAS $>$ CVAAS $>$ ETAAS $>$ FAAS.

Since vapor generation techniques (HGAAS and CVAAS) are not the topic of this article, only speciation by ETAAS and FAAS techniques will be discussed briefly. Both techniques have been used in the past as detection methods for chromatographic separation techniques, as discussed by Ebdon and Hill,\textsuperscript{(302)} but have been overtaken by more powerful detection techniques such as inductively coupled plasma mass spectrometry (ICPMS). Although FAAS and GFAAS are not very suitable to be coupled directly with chromatographic separation techniques, their combination with nonchromatographic separation methods is more straightforward, as we have discussed already for the case of preconcentration. Techniques such as solvent extraction or solid-sorbent extraction used for preconcentration can also be used for speciation purposes, for example, when the separation process is selective for one oxidation state of the analyte. Such combined methods, using GFAAS for speciation analysis, have been reviewed by Das and Chakraborty.\textsuperscript{(303)}

Often such nonchromatographic separation methods can be automated by using FI manifolds. When used for separation, FI provides only limited separation power, which mostly is exploited for binary separation of the type retained/not retained, for example, for preconcentration. While such a technique is not very well suited to separate a great number of analytes, it seems well fitted for screening purposes requiring high sample throughput. Further, for cases where the separation of species can be reduced to two, FI can be successfully used for speciation analysis. This is actually true for many cases of speciation of oxidation states of metal ions and metalloid ions, where the chemistry of these elements normally allows only for the presence of two different oxidation states in the presence of each other, at least under normal environmental conditions. Methods have been developed for the determination of As(III)–As(V),\textsuperscript{(304)} Cr(III)–Cr(VI),\textsuperscript{(305–309)} Fe(II)–Fe(III),\textsuperscript{(310)} Sb(III)–Sb(V),\textsuperscript{(311)} Se(IV)–Se(VI)\textsuperscript{(312)} and V(IV)–V(VI).\textsuperscript{(313)} The approach of binary separation can also be used for those cases where interest in the degree of speciation can be reduced to a binary differentiation. For example, such limited separation is useful for the differentiation of inorganic and organic species, labile and stable complexes, bound and free element species or the particulate and dissolved part of the analyte. This approach can also be applied for cases when other characteristics of the species can be grouped into two different categories, such as toxic/nontoxic. In this area of binary speciation, methods have been developed for the determination of free and complexed Cu\textsuperscript{(314)} and of free and complexed Al.\textsuperscript{(315)}

\textbf{4.2 Soils, Sediments, Sludges, Coal, Dust and Other Solid Materials}

A variety of widely differing solid materials will be discussed here together, simply because they have some common steps in their analytical procedure while differing in others. Solid materials such as arable soils, contaminated soils, sediments from rivers, lakes and seas, atmospheric dust and waste materials such as sewage sludge, ashes and other solid wastes are collected as samples from different compartments of the environment in order to gain information about the status of that compartment or to learn about the fluxes between them. The emphasis of environmental analysis is on the anthropogenic part of these fluxes and on the impact of such fluxes on the biosphere.

With respect to soils, in addition to the native content, various amounts of metals and metalloids are supplied
to the soil by dry and wet atmospheric deposition, by agronomic practices via fertilizers, sewage sludges or irrigation water, and so on and by waste discharges or waste disposal. For certain metals the anthropogenic proportion constitutes only a fraction of the natural amount, for others it can be the exclusive source. These metals and metalloids enter the food chain mainly via plant uptake.

Human activities are connected with the ‘production’ of waste materials including municipal solid wastes, industrial by-products, sewage sludge, dredged material, wastes from mining and smelting operations, filter residues from wastewater treatment and atmospheric emission control, ashes and slags from burning of coal and oil and from waste incinerators. All these wastes pose most challenging problems (e.g. when disposed of on land), creating a potential source for contamination of the soil and the groundwater.

The materials on the lake, stream and ocean floor, known as bottom sediments, are both a sink and a source of contaminants. Sediment-associated contaminants can be transported by resuspension of sediment particles, may accumulate in the food chain or may affect the health of biota and water quality in aquatic ecosystems. Knowledge of the character of the sediments and the fluxes involved is necessary for an understanding of environmental cycles but also in the development of techniques for remediation of aquatic ecosystems or the disposal of the sediments in the dredging of harbors and waterways.

With respect to atmospheric emission, monitoring frequently starts at the raw material stage. For example, emission monitoring of coal-fired power stations, coke works, incineration plants or cement furnaces starts with the analysis of the coal or waste materials to be burned. For the mass balance for such thermal reactors the different streams must be analyzed. While the mass carried with the scrubbed gases is important for the actual emission, the dusts collected in cyclones and electrostatic separators, ashes and other combustion residues such as slags must also be analyzed to characterize the complete system.

Air pollutants can occur in gaseous, fluid (dissolved or suspended) or solid form. Air must therefore be considered as an inhomogeneous, multiphase aerosol, whose composition is subjected to considerable spatial and temporal variations. With respect to metals and metalloids, the gas phase is only of limited interest, since only mercury and a small number of volatile species occur as gases or vapors, especially close to hot emission sources. The liquid phase (rain, snow, etc.), also termed wet deposition, belongs analytically to the area of water, which has been discussed in section 4.1. The analysis of air, with the restrictions mentioned already, is thus largely limited to the analysis of airborne dusts. Looked at globally, the bulk of airborne particles (approximately 90%) are derived from a number of natural sources (terrestrial, marine, volcanic, biogenic), whereby salt from the oceans makes the largest contribution with about $10^4 \text{ t a}^{-1}$. Looking more specifically into metal emission, the view changes drastically, with a clear dominance of anthropogenic sources of the most important trace elements such as As, Cd, Cu, Cr, Pb and Zn on the global scale. The anthropogenic sources of particle emissions (combustion, industrial, automobile) are by no means evenly distributed, but are related to the typical conurbations in which human activity is the most pronounced. Owing to the relatively high population and industrial density, such sources are concentrated in the northern hemisphere, but because of long-range transport globally these sources have an impact on a large proportion of the population in the form of pollution.

4.2.1 Sampling of Solid Environmental Materials

Obviously, the procedures for sampling, sample homogenization and preparation of such widely differing materials are correspondingly manifold, and cannot be discussed in great detail here. Before one even starts to discuss analytical details, the exact purpose of the analysis should be clarified, since the type of information needed is decisive for the selection of the method. Three general procedures can be distinguished for these samples, determination of (a) the total concentration of an element, (b) the extractable portion and (c) individual species, especially organometallic compounds; the boundaries between these procedures are naturally flexible. The decision about which method to select is driven by the emphasis given to topics such as risk assessment, evaluation of bioavailability or toxicity, pollution control, baseline mapping and transport phenomena. The interested reader is referred to introductory monographs and review articles on the analysis of soils, sediments, sludges and other waste products and airborne particulates and on speciation analysis in soils and sediments and to general treatises on environmental analytical chemistry, discussing such questions in more detail. The selection of the determination technique (FAAS, GFAAS, etc.) is simple in comparison. It is largely determined by the concentration of the analyte and also by the nature of the matrix.

4.2.1.1 Sampling of Soil, Sediments, Sludges and Solid Waste Materials

The problem for sampling soils, sediments, sludges and other waste materials is the removal of a few grams that should be representative of the situation being investigated from a material that is present to the extent of tons or cubic meters. Meaningful sampling of such
heterogeneous media requires an understanding of the spatial and temporal variations, which is a prerequisite for answering the basic questions of how many samples are needed and where they should be taken. In the case of soils and sediments the planning of sampling has to start with a site investigation making use of available (e.g. historical) information, which could help to build hypotheses and conceptual models. A site characterization follows, consisting of two major steps, namely site observation and subsequent site mapping. Such site characterization is a multimedia, multidimensional, multidisciplinary effort, that requires vigorous communication among all of the principal parties involved and often includes preliminary sampling. Unfortunately, no checklists are capable of addressing all of the important issues and factors that influence the sampling and analysis of such materials. However, field guides and handbooks are available for soils\cite{334} and sediments\cite{344} that are helpful in defining the task. From all this information a sampling strategy is built, leading to a sampling network design. Depending on the required information, the sampling strategy must consider the local inhomogeneities in the horizontal plane of the sampling site, the dependence of the element distribution on the depth of sampling and possible seasonal variations.\cite{347,345,346} A number of statistical procedures have been elaborated to facilitate representative sampling or to estimate the analytical uncertainty due to sampling errors, for example, in order to characterize contaminated areas.\cite{347–352} Usually a large number of individual samples of the material being investigated are taken from different places (e.g. 25 samples from an agricultural field not bigger than 5 ha) and then combined into a composite sample. The advantages of composite sampling are that it reduces the cost of analysis and provides an estimate of the mean concentration. Its disadvantages are a loss of information about variation and the time required for such pretreatment. In order to avoid sampling errors\cite{353} due to the heterogeneity of the material and the effect of particle size on element distribution,\cite{354,355} one has to follow certain rules dictated by the particulate sampling theory, such as that developed by Gy.\cite{356} In order to create an analytical subsample, the composite sample has to be homogenized and reduced in size. Different techniques for such homogenization exist, such as cone and quartering, sectorial splitting, riffing, milling and sieving. Sample preservation then depends on the analysis. In the case of total element determination the material is often dried and for other cases the samples are simply cooled to 4 °C or frozen (usually at −20 °C). The problems of sampling and sample preservation naturally become even more complex when element species are to be determined.\cite{357,358} In any case, the uncertainty introduced by sampling of such heterogeneous materials supersedes all other following contributions,\cite{339,359,360} and therefore needs careful evaluation in order to create meaningful data. It should be mentioned once again that this area is regulated by national and international rules, for example, for the sampling of soil (ISO-TC 190/SC2), sediments (DIN 38 414-11/1987) and sludges (DIN 38 414-1/1986).

4.2.1.2 Sampling Dusts Collecting the sample is the most critical step in the analysis of dust, as it is for other samples in environmental analytical chemistry. For the analyst, air is a practically infinitely expanded aerosol on which random investigations must be performed according to defined spatial and temporal regulations. The number and size of the random samples, as well as the place, time and sequence of sampling, are decisive for a representative statement on the relationship between quantity of material, space and time. A number of authors have treated the subject of sampling dusts very thoroughly in review articles and book contributions. This has been done either in general\cite{361} or in selected areas such as the free atmosphere\cite{316} or at the workplace.\cite{362–364}

For the investigation of trace substances in the free atmosphere, the temporal and spatial distribution of sample collection in an area to be investigated must be matched to the meteorological conditions, such as wind direction, wind speed, air temperature and humidity. The length of an investigation program, the measurement frequency and the density of monitoring stations have to be carefully selected. Frequently, the concentration of constituents determined by a measurement program is influenced by the geographical location of the monitoring station. This is typical in areas where dust is whirled up strongly or close to the coast where the constituents of the sea spray become clearly noticeable. The extent to which meteorological conditions can influence sampling can be seen when the wind velocity is high, causing turbulence at the sampling port or even causing an under pressure so that the collected sample material can be transported back to the outside.

Dust cannot be sufficiently characterized by only its general composition, but physical and chemical forms (species) have to be differentiated;\cite{365,366} the morphological composition of dust can be very heterogeneous depending on the origin of the particles\cite{366,367} and the various forms can have markedly varying physiological activity. Smooth globular grains have a much smaller surface area, and are thus less reactive than needle-shaped, fine crystalline particles. Apart from the morphology, the size of particles, ranging between 0.001 and 150 µm, also has a decisive influence on the physiological activity. Particles smaller than 10 µm can enter the lungs of humans or animals, while larger particles can be filtered out. Dust samples often show a particle size distribution with characteristic maxima at two or three different particle sizes (bimodal, trimodal size distribution) depending on
sources and history. A further criterion is the solubility, which decides whether an element can directly enter the nutritional chain, or whether it is initially sedimented.

For sampling aerosols, two different approaches are available: procedures that use suction and those that do not. For the latter, various collectors for dust precipitates are available, which again are often regulated by national standards. In general, such devices do collect preferentially larger particles since these fall out more easily than smaller particles.

For sampling under suction, measurement and maintenance of a constant volume stream by the air pump are essential components of sampling. The sampling method most widely used is the high-volume sampler, which has been standardized in many countries, and operates at sampling rates between 40 and 100 m³ h⁻¹. For sampling gaseous constituents, wash bottles with a suitable absorber solution or tubes being coated with a specific agent, so-called denuders, are frequently used. To separate dust from the air, flat membrane filters made of cellulose materials are most suitable owing to their low and constant element blank values. In high-volume samplers large filters can be used, which later can be cut to several aliquots that can be used for (a) various types of analysis, (b) replicates, (c) sharing samples with other groups or (d) storing them as ‘backup’ samples. Fiberglass filters do allow a larger volume of air to be taken through, but are less useful for trace analysis of airborne dust because of their high and often markedly varying element blank values. Preseparating inlet systems are available for such samplers, which exclude particles larger than 10 µm, for example, in a cyclone. Cascade impactors most often are used for size separating sampling, which are available with 4–9 stages having size ranges between 0.02 and 20 µm.

Sampling for emission measurements is usually performed directly in the stack or chimney, for example, of a power station or a waste incineration plant. The difficulties to be expected in taking a sample representative of the total mass flow under isokinetic conditions can be seen from the example of a stack gas stream of several 100 000 m³ h⁻¹ at a temperature of up to 300 °C and with a varying dust content from milligrams to grams per cubic meter. For trace analysis, the problems of the level and scatter of the blank value and also contamination during sampling can additionally be detrimental to the results of the examination. This is more so the case for emission measurements since cellulose filters cannot be used, owing to the high temperatures at the sampling point, and quartz wool must preferentially be used.

For the measurement of dust at the workplace two different strategies exist, using either stationary or personal dust measuring instruments. Stationary measuring instruments are similar to those used for measuring in the free air and have the advantage that the air throughput is relatively high at about 20 m³ h⁻¹, permitting a sampling period of only a few hours. The relatively small personal measuring instruments, on the other hand, have an air throughput of only about 120 L h⁻¹ (corresponding approximately to the volume of air breathed), so that sampling is required for the entire length of a working day to collect sufficient material for the subsequent chemical analysis. Membrane filters made of cellulose materials are used preferentially for dust measurements at the workplace.

In addition to the collectors mentioned so far, which are largely standardized, there is a wide range of collectors designed for special applications, such as the investigation of automobile exhaust gases or soot from Diesel engines, or those that are specific for the subsequent analytical technique. Among these in particular are those developed for GFAAS procedures in which a probe made of porous graphite is used as a filter and inserted directly into the atomizer, or the inner wall of the graphite tube itself is used for collection of aerosols either by impaction or by electrostatic deposition. Owing to the high sensitivity of such in situ sampling techniques, very short collection times are possible so that the measurement can be performed virtually in real time. The disadvantages are that only one element can be determined per sample collection, except in simultaneous spectrometers, and that no sample is available for further evaluation. In general, procedures of this nature must therefore be seen as complementary to the standardized collection procedures and not as alternatives. A list of methods approved by United States Environmental Protection Agency (USEPA) was given by Kao, but those for metals are few, however.

4.2.2 Determining the Total Concentration of Analytes

4.2.2.1 Total Dissolution

For the determination of the total analyte concentration in a test sample, very harsh decomposition procedures are required, which are aimed at the total dissolution of the sample. Soil and dust samples exhibit considerable variations in mineralogical and chemical composition, including very resistant materials, making the task of total dissolution a difficult one. The total dissolution procedures available for such samples are either fusion methods using sodium carbonate or lithium metaborate or acid digestions in the presence of hydrofluoric acid and frequently also perchloric acid. Although such harsh procedures are time-consuming and the use of such dangerous acids demands special safety measures, they cannot ascertain the total dissolution of a number of minerals, such as cassiterite, chrome, zircon, rutile, monazite and corundum. Apart from incomplete
dissolution, formation of volatile fluorides is another possibility for analyte loss for a number of elements such as antimony, arsenic, boron, germanium and silicon (which should be removed in this way).

Since fusion methods lead to high total salt concentration with a corresponding risk of contamination and interferences in GFAAS due to the high background signal, wet digestion methods are more popular in connection with AAS. However, often the difficult matrix cannot be dissolved by a single-stage dissolution, but calls for a combined multistage digestion using oxidizing acids (nitric acid, perchloric acid, sulfuric acid, hydrogen peroxide) and hydrofluoric acid.\(^{(386, 390)}\) If necessary, dry ashing can be performed in advance\(^{(391, 392)}\) and if insoluble, fluoride-containing residues are produced during digestion, they can be taken back into solution by the addition of boric acid.\(^{(390)}\) A comparison study concluded that the combination of an acid decomposition with final fusion of insoluble residues is the best method for the hard to extract elements Cr, Y and Zr.\(^{(378)}\)

Membrane filters normally used nowadays in dust collectors dissolve in nitric acid and also in organic solvents such as benzene.\(^{(371)}\) On the other hand, quartz wool used as a filter medium for emission measurements usually requires digestion in nitric acid or hydrofluoric acid under the addition of hydrogen peroxide.\(^{(395)}\)

For the digestion of coal and coal ash often a pressure digestion with hydrofluoric acid–nitric acid\(^{(394, 395)}\) is used, preferentially with the addition of a strong oxidant such as perchloric acid or ammonium peroxodisulfate.\(^{(392, 394)}\) Less common is a digestion with perchloric acid (72%) alone, which requires a good deal of attention.\(^{(396)}\) The combustion of coal in an oxygen bomb\(^{(397)}\) or oxygen combustion\(^{(398)}\) and fusion with lithium metaborate\(^{(399)}\) have also been described. In a review article, Mills and Belcher\(^{(400)}\) discussed in detail the problems of sample pretreatment and digestion for the analysis of coal and ash.

4.2.2.2 Partial Dissolution In general, total dissolution is a difficult task for many samples and, once achieved, leads to high salt concentrations. The latter may pose problems with nebulization in FAAS or create strong background attenuation in GFAAS. The high matrix concentrations require regular blank controls to be performed, and frequently the calibration solutions must be matched to the matrix contents. Owing to such problems, it is very common to avoid ‘total dissolution’ in environmental analysis. Instead, an extraction with a strong mineral acid such as boiling aqua regia under reflux is preferred.\(^{(401–406)}\) This is justified on the assumption that heavy metals insoluble in aqua regia will probably not be relevant for environmental chemistry, at least not in the short term. With the exception of a few cases, a valid approach seems to be that the aqua regia-resistant compounds will not be taken up by plants and cannot be dissolved by water or bacteria.\(^{(405)}\)

4.2.2.3 The Microwave Oven Option Microwave-assisted digestions (MWDs) have found rapid acceptance in the environmental analysis of solid samples.\(^{(407–409)}\) The major advantages of MWDs are reported to be the substantially shorter digestion times,\(^{(410, 411)}\) the lower risks of contamination, the reduced reagent requirements\(^{(412)}\) and the lower risk of losses.\(^{(413)}\) Different acids and acid mixtures have been investigated, mostly using nitric acid or mixtures of hydrochloric acid and nitric acid\(^{(414–416)}\) or aqua regia\(^{(417–419)}\) but also including hydrofluoric acid\(^{(415, 420–423)}\) and perchloric acid.\(^{(424)}\) While the careful selection of the acid mixture and the operational parameters was a prerequisite for a successful digestion until recently,\(^{(425)}\) the development of systems with automatic pressure and/or temperature control\(^{(426–428)}\) have significantly reduced such requirements. Owing to the high effectiveness of MWDs it has also been possible to incorporate them on-line in a flow system with FAAS\(^{(429–431)}\) or GFAAS\(^{(432)}\) detection.

For the actual determination by AAS, we should always remember the general rule that the best results can be expected when the optimum concentration range is used. This means that FAAS is only suitable for the determination of higher analyte contents, and not for trace analysis. Owing to the frequently complex and refractory matrix, particularly when the digestion is complete, the hottest possible flame should be used in general and the measurement should be performed as high above the burner slot as possible. In other words, the measurement should be optimized for minimum interferences and not for maximum sensitivity. Aqua regia extracts can be analyzed by FAAS relatively free of interferences, since the element concentrations normally to be expected in soil, sediment and dust samples are so high for numerous analytes that the sensitivity of FAAS is fully adequate. Some selected publications of such applications are given in Table 9.

The alternative way of avoiding interferences is higher dilution followed by GFAAS determination. The concentrations of elements in soils, sediments and sludges which are considered to be tolerable depend strongly on regional regulations, but in general they are between 1 and 300 mg kg\(^{-1}\) for agricultural soils and about a factor of 10 higher for sludges.\(^{(435)}\) Owing to the dilution introduced by the acid extraction, such soil concentrations produce solution concentrations between 10 and 3000 µg L\(^{-1}\). Even one tenth of the tolerable concentration is still above the detection limit of GFAAS for most elements. The partial dissolution and the high dilution factor ensure that the matrix concentrations in the sample solution are often

very low, so that the matrix remaining in solution might be considered relatively simple. Because of this, method development can often be focused towards fast analysis and high sample throughput. Nevertheless, STPF conditions and ZBC frequently have to be used. In any case, the absence of interferences should be checked, for example, by recovery studies using reference materials. In the meantime, reference materials have been produced for which, in addition to the certified total concentration, information is also provided on the fraction that can be leached by aqua regia, for example, soil samples NIST SRM-2709 and SRM-2711, Bureau Communautaire de Référence (BCR) CRM 141R, 142R and 143R and sewage sludge samples BCR CRM 144R and 145R and 146R. Further improvements, such as a reduction of the background attenuation, can be obtained by in situ ashing with air or oxygen or the addition of hydrogen to the purge gas. Aqueous calibration solutions can often be employed in combination with matrix modification. Special attention has to be paid to particle size and density effects, which might call for particle size reduction, which could then reduce the benefit of reduced sample preparation owing to the application of these techniques are the much lower sample requirement and the increased sensitivity. The application of the STPF concept and ZBC are quasi prerequisites for accurate analyses, because the matrix often has a substantial influence on the appearance time and the signal profile. A number of authors have attempted to simplify the introduction of the solid dust samples by punching small disks from the filter and analyzing directly. The precision of this procedure is nevertheless poorer than when the filter is homogenized in a mill.

In contrast to direct solids analysis, the analysis of slurries is more flexible, and precision and trueness are better for the analysis of slurries in comparison with solids, especially when they are homogenized by an ultrasonic probe directly mounted to the autosampler of the GFAAS instrument. Further improvements, such as a reduction of the background attenuation, can be obtained by in situ ashing with air or oxygen or the addition of hydrogen to the purge gas. Aqueous calibration solutions can often be employed in combination with matrix modification. Special attention has to be paid to particle size and density effects, which might call for particle size reduction, which could then reduce the benefit of reduced sample preparation owing to the application of these techniques are the much lower sample requirement and the increased sensitivity. to the absence of a predigestion. For the same reason, the atomization of slurry samples by FAAS, which has been performed with sample introduction by FI (450,495,496) has not attracted great attention owing to the restriction to very fine particles or analytes that can be easily extracted into the aqueous phase during the preparation of the suspension.

### 4.2.3 Selective Extraction of Individual Constituents and Bonding Forms

The determination of the total concentrations of analytes cannot give the right answer to many environmental questions, such as evaluation of the exposure of plants and animals to pollutants, evaluation of the fertility of agricultural soil or risk assessment for a waste dump site. Rather than the total concentrations of elements, the part which is bioavailable to plants and animals, the part which is leachable and mobile and thus can move away from the site and reach the aquifer and so on is of interest for such studies. For this type of element speciation, leaching procedures using a variety of differing reagents, either in a single step or in a sequential extraction scheme, have been used successfully for decades. The choice of extractant will depend not only on the element in question but also on the soil type, the crop or animal species, the weather and the technique for determination. The list of extractants which have been used is correspondingly long and sequential extraction schemes using a set of extractants are also empirical guidance.

</tbody>
</table>

Despite these limitations, they are often specific enough to provide the information necessary for making diagnostic or managerial decisions. However, the different extractants and the numerous extraction schemes used significantly hinder the comparability of results between different studies. In order to overcome such problems, harmonized procedures have been developed, such as those under the auspices of the BCR (509–511) for the single extraction with ethylenediaminetetraacetic acid (EDTA) or acetic acid and a sequential extraction scheme using three steps, which is given in Table 10. The use of microwave heating for speeding up the extraction procedure (512) can also lead to improved reproducibility. In addition, reference materials are now available for which not only the total element content but also extractable portions are certified (513–516).

For the determination of the element by AAS, it is of no great consequence whether the sample material is a soil, a sediment, a sludge or a waste material. Since...
only relatively small element concentrations are extracted during the leaching, especially with weak extractants, FAAS is only sufficiently sensitive for a few elements, such as Al, Ca, Co, Cu, Fe, K, Li, Mg, Mn, Na, Sr, Zn. This situation might be different for airborne particulates, for which the extractable concentration of some more metals (e.g., Cd, Cr, Ni, Pb) might be sufficient for their determination by FAAS. However, in many cases for elements such as Ag, As, Cd, Cr, Mo, Ni, Pb, Se, Sb, Sn, Te, Ti, V, it is usually necessary to apply GFAAS or other more sensitive techniques. Owing to the considerably lower total salt concentration, the matrix influences are far less pronounced than with a complete digestion, at least for those extractants that do not add significantly to the total salt concentration.

4.2.4 Speciation Analysis in Soils, Sediments, Sludges, Dust and Other Solid Samples

The determination of redox species and organometallic compounds in solid materials, such as soils, sediments and sludges, is preceded by an extraction procedure, and in this respect is similar to the determination of bioavailable species. The determination of the individual species from the extract is hardly different from the analysis of water. In rare cases where FAAS is sensitive enough for speciation analysis, the separation procedure for the species is coupled with preconcentration, for example, for the determination of Cr(VI). The use of GFAAS for speciation analysis has been reviewed by Das and Chakraborty. As has already been pointed out, GFAAS is not a very suitable technique to be coupled with chromatographic separation since all attempts to run GFAAS in a continuous mode were unsuccessful and coupling between these two techniques has to be done via either a fraction collector or a flow-through subsampling interface. These interfaces require careful synchronization and optimization of the flow rates and sampling intervals, which significantly reduces its applicability. Other techniques, which can be operated continuously, such as vapor generation techniques (CVAAS, HGAAS) or plasma techniques, such as ICPMS, are much better suited.

For those cases where GFAAS has been used for speciation analysis of soils, sediments, sludges and dust samples, mostly nonchromatographic separation procedures have been used. These include the extraction of Cr(VI) in a weakly alkaline medium, the extraction of tributyltin oxide with n-hexane–dichloromethane or isooctane and its back extraction with nitric acid. The selective extraction of chelates has been applied for the species determination of As(III), Sb(III) and Cr(VI).

The determination of Cr(VI) in welding fumes is one of the most important industrial hygiene examinations owing to the toxicity of this species. The influence of the collecting procedure, the welding fumes themselves, the storage period and the analytical procedure have been investigated in detail. While the Cr(VI) content of fiberglass filters did not appear to change over several weeks of storage, Rohling and Neidhart found that during collection Cr(VI) is reduced by SO₂, which can lead to severe losses of Cr(VI), depending on the length of the collection period. Girard and Hubert showed that the Cr(VI) can be quantitatively recovered from the filter medium by extraction with acetic acid–sodium acetate. Brescianini et al. eliminated the interferences caused by large quantities of calcium, iron and sodium during the determination of chromium by GFAAS by separating the analyte on an ion exchanger.

Moreover, ion exchangers, chelating resins and other solid sorbents have been utilized in batch or column procedures to distinguish between different arsenic species such as As(III) and As(V), Cr(III) and Cr(VI) and organotin compounds.

4.3 Biological Materials

Biological materials are investigated not only for environmental analysis, but also for reasons of biological, biochemical or biomedical analysis, toxicological, pharmaceutical, nutritional and clinical analysis, food analysis or biogeochemical analysis; the information sources available about sampling and analysis of such materials are correspondingly spread over a wide range of disciplines. For the purpose of environmental analysis, it is seldom the biological material itself which is the primary target of interest (as in toxicological or biomedical analysis), but its function as an indicator for the environmental compartment from which it was taken. In this function, biological materials are collected from different compartments of the environment. For the same reasons, other inorganic materials are collected, to gain information about the conditions of that particular compartment with respect to being part of a hostile biosphere or to learn about the exchange and fluxes of materials (pollutants) between different compartments or different parts of a compartment. With respect to biological materials, the primary concern is the entrance of pollutants into the food chain and the concentration of such pollutants by bioaccumulation. For plants and vegetable products, sources of pollutants are the soil on which they are grown, fertilizers, crop protection agents, insecticides and pesticides used and atmospheric precipitation, especially due to the proximity of roads or industrial installations. Animals (and humans) are influenced by the environmental conditions either directly (e.g. aquatic environment) or indirectly by
taking up pollutants (e.g. with their nutrition or drinking water) from that environment.

Those biological objects and systems which respond very sensitively to anthropogenic influences on the environment can be used as bioindicators for the detection of the presence of pollutants and biomonitoring can be used as a more quantitative method for the determination of the pollutants present. For example, low-level plants such as lichens and mosses accumulate large amounts of heavy metals, because their unprotected surfaces provide ion-exchange facilities which allow the effective adsorption of metals. The complexes then formed between the metals and the negatively charged organic groups are fairly stable. The accumulation of heavy metals on such plants is the basis for their use as bioindicators of atmospheric pollution. The problem with biological materials as samples for environmental analysis is biological variation, which hampers the assessment of baseline concentrations and the interpretation of analytical results.

The analysis of biological materials by AAS has a long history. While the reasons for analyzing biological materials are numerous, the different objectives are secondary for the selection of methods and techniques applied to the determination of elements in these materials by AAS. Review articles have been published by Slavin on the use of FAAS and GFAAS for the analysis of biological materials in general, by Hanlon on plant analysis, by Rains on foodstuffs analysis, by Pritchard and Lee on agricultural samples, and by Hoenig and Guns on environmental and biological samples. Apart from review articles on single elements already mentioned (see section 4), numerous other minerals and trace elements are treated in the monographs Quantitative Trace Analysis of Biological Materials edited by McKenzie and Smythe and Trace Minerals in Foods edited by Smith. Trace Element Analysis of Biological Specimens edited by Herber and AAS in Occupational and Environmental Health Practice written by Tsalev. Markert gives an overview of plant analysis and the use of bioindicators and Kiceniuk and Ray treat the analysis of contaminants in edible aquatic resources. Annual reviews on the determination of elements in biological materials appear in the Journal of Analytical Atomic Spectrometry.

4.3.1 Sampling and Sample Pretreatment of Biological Materials

Again, an analyst should not waste time in investigating a laboratory sample whose history is not known in complete detail and is not documented. Sampling is of decisive significance for the accuracy of the analyses of biological materials. Some problems are common with the sampling of other sample materials, for example, selection of appropriate locations, techniques and designs, errors due to the limited numbers of samples and contamination due to the tools used. However, the main problems are the high biological variability and biotic and abiotic influences on the availability of the sample material and on the reproducibility of its analysis. For example, such influences are as follows:

1. the exposure of the biological species and its behavior with respect to accumulation;
2. the time of sampling with respect to the season and to the phenological state of development of the biological species;
3. fluctuations or trends in the abundance or composition depending on age, gender or physiological state or morphological and genetic variability;
4. fluctuations between sampling locations with respect to edaphic or microclimate factors and exposure to emission;
5. errors due to a selective sampling procedure, favoring individuals or groups, having special characteristics.

For the sampling of plant materials, this means that one has to decide which parts of the plant to sample (roots, leaves, needles, etc.), their location with respect to the soil (distance from the ground) and their exposure (free-standing plant, plant from a forest ecosystem). Furthermore, the time of exposure depends on the age of that particular sample, which must be known (e.g. to create comparable results when sampling tree needles of different ages). Depending on the questions to be answered by the investigation, one has to decide whether external contamination of the plant material by soil and precipitation has to be removed before analysis or not. If it has to be removed, the cleaning procedure must be designed to remove only the external contamination, and to avoid leaching the plant components. If external contaminants should not be removed, the sampling procedure has to assure the retention of those components.

When sampling biological materials of animal origin, a practical method of capture, not prone to contamination, and in accordance with ethical rules, is a prerequisite for using that species for environmental analysis. Depending on the type of sample (body fluid, soft tissue, hard tissue) and whether it can be collected without killing the animal (e.g. bird feathers, egg shells, body fluids), one has to account for changes in element distributions due to stress or postmortem changes (autolysis, etc.). Contamination risks are especially high when internal organs have to be taken by dissection or when blood samples have to be analyzed.
These and other sampling and presampling factors cannot be discussed in detail here. Comprehensive information on this subject has been published by Jones and Case, Keith and Markert. In the laboratory, the sample must be homogenized, conserved and typically stored. Naturally, all precautions to prevent contamination from tools, containers, the laboratory atmosphere and losses due to volatilization or adsorption must be scrupulously observed. For the homogenization of plant and animal tissue samples, cutting and mixing tools that have stainless-steel parts are often used. Contamination can be expected from such tools, especially for Fe, Cr and Ni.

4.3.2 Digestion Procedures

Plants and biological tissues are usually decomposed for the determination of total element concentrations by AAS techniques, although they can be determined also by direct techniques using solid-sample introduction or slurry sampling. The main reason for using routine decomposition techniques is concerns about the homogeneity of sample masses as small as a few micrograms. In addition, the samples often have to be prepared as powders and such pretreatment may take as long as a fast decomposition technique.

For the decomposition of various biological materials, a wide selection of methods have been developed, including dry ashing, wet digestion, pressure digestion and MWD. The selection of an appropriate digestion procedure depends on the analyte, the sample matrix and the method of determination. In general, atomic spectrometric techniques do have a much higher tolerance against residual carbon after the digestion than other instrumental techniques such as electrochemical methods, since residual matrix components can be destroyed during atomization. The amount of residual carbon which can be tolerated by different AAS techniques decreases in the order FAAS > GFAAS > HGAAS/CVAAS. Digestion solutions, which are clear and free from particles in general, fulfill the requirements for FAAS.

In the 1960s and 1970s, dry ashing was widely used, since relatively large sample aliquots can be ashed (up to 20g) and taken up in a minimum volume of acids. In this way, many trace elements could be determined by FAAS, which was the only technique available at that time. Dry ashing can be performed directly or with the addition of ashing aids such as magnesium nitrate or small amounts of nitric acid and sulfuric acid, usually at 450–550 °C. Accurate temperature control, often not possible by reducing the uptake rate of the nebulizer because of their high viscosity or by other interference effects.

By using low-boiling mineral acids, complete destruction of the organic material is not often possible by open digestion. However, it has frequently been shown that many elements can be extracted from biological materials, even with diluted mineral acid, without complete destruction of the organic material. In any case, such methods...
cannot be generalized and have to be verified for the matrix being investigated. In general, animal materials cause fewer problems than plant materials, and elements such as Ca, Cd, Cu, K, Mg, Mn, Na, Pb and Zn can be more easily extracted than Al, Cr, Fe, P and Si.

While the application of high-boiling acids for AAS is problematic, it is the oxidation power which is needed to decompose totally the complex organic matrix of some of the environmental samples. Of the mineral acids that are compatible with AAS (e.g. HNO₃, H₂O₂, HCl and HF), only the first two develop sufficient oxidation power but, because of their low boiling points, the oxidation power is not enough for complex matrix-containing substances, which are difficult to digest, such as fat. In order to raise the boiling point of these acids and therefore their oxidation power, the wet digestion procedure can be performed under pressure. There are many advantages of a pressure dissolution compared with open acid dissolution. Since the pressurized decomposition vessel represents a closed system, the loss of volatile elements is avoided, in addition to the risk of contamination from the laboratory environment. Depending on the pressure which the system can withstand, either temperatures in the region of 200 °C (medium pressure, ≈80 bar) or >500 °C (high pressure, ≈130 bar) are possible. Under such harsh conditions, the total decomposition of complex matrices is possible, and organic materials can be decomposed with very little residual carbon remaining in the digest (<1%). The disadvantage of pressure digestion in autoclaves (‘bombs’) is the small amount of organic matter which can be treated. The special problem with biological materials is that large amounts of gaseous products (CO₂) are formed during the digestion. As a result, the maximum sample mass that can be loaded into such pressure vessels is limited to about 200–500 mg for a vessel volume of about 100 mL for medium-pressure systems and about 1 g for high-pressure systems. Using a medium-pressure system, operated at 170–180 °C, the optimum digestion time for biological materials with nitric acid is about 3 h. For a high-pressure digestion system, the effective digestion time can often be reduced to about 1.5 h. About 2 mL of nitric acid are generally sufficient for a pure carbon content of 100 mg, independently of the type of biological sample. For determining the maximum sample mass, one has to consider that the carbon content of dried biological material varies between 35 and 50% for plant materials and between about 45 and 55% for animal materials with the exception of oils and fats that have carbon contents between 74 and 78%. Nitric acid alone is sufficient for complete digestion under high pressure for most elements and biological sample types. Some samples (e.g. some plant samples, mussels) contain high amounts of silicate, requiring the addition of hydrofluoric acid. For more details, introductory papers and review articles on pressure digestion should be consulted.

Since the end of the 1980s, these various digestion techniques have been increasingly replaced by microwave-assisted acid digestions which are frequently performed in closed containers and under low (up to 40 bar) to medium pressure (up to 80 bar). The major advantages compared with conventional digestion techniques include the reduced time and reagent requirements, the lower blank values, the reduced risk of analyte losses, the possibility of automation and the ability to digest a number of samples at the same time. When comparing the time required for a conventional pressure digestion (CPD) and for a MWD, one has to consider that the digestion time is drastically reduced in a microwave system. This is shown in Table 11.

The most important difference is the fast heating for MWD. In addition to the time advantage for MWD, there is also an advantage with respect to the wear of materials. The digestion vessels in CPD are under heat and pressure stress for a much longer time than the vessels in MWD systems. Therefore, the vessels in CPD systems wear out earlier, and contamination due to sorption/desorption processes are more pronounced than in MWD systems.

The time gain with MWD is further reduced when the digestion cannot be performed in a single step. This is the case when either the gases produced during the digestion must be vented or reagents have to be added after the first step in order to complete the digestion. Especially under low-pressure conditions, the oxidation power of nitric acid is not sufficient for all types of material. Materials rich in fat are especially difficult to decompose and often require the addition of additional oxidants such as hydrogen peroxide. Stronger oxidants such as sulfuric acid and perchloric acid are (besides their incompatibility with GFAAS) also not very useful in MWD. Typically, they develop their oxidizing power at such high temperatures (above 250 °C) that the polymeric material often used for the vessels breaks down. When a single-step digestion is the target for method development, the method requires careful optimization.

with respect to the matrix. Chemometric techniques have been applied for this purpose. State-of-the-art MWD systems having temperature and/or pressure sensors for each vessel require much less method development and optimization, since the digestion can be automatically operated under optimum conditions. Some systems use quartz vessels that can be used at temperatures above 200 °C and allow pressures up to 80 bar.

In addition to these widely used digestion procedures a number of techniques have been proposed that have not come into general use, but can occasionally be of interest as comparative techniques or for a special combination of analytes and matrices. A comparison of such techniques with respect to their characteristics is given in Table 12. Since FAAS and GFAAS methods do not require the highest digestion quality with respect to completeness of the destruction of organic materials, even the incorporation of MWDs into flow systems has been successfully performed for some biological materials. A review of such methods was presented by Burguera and Burguera. Solubilization of materials with tetramethylammonium hydroxide (TMAH) has been used successfully, sometimes under microwave assistance, especially in combination with speciation. Other less frequently used techniques are based on combustion in a stream of oxygen in a closed system or on intense infrared (IR) irradiation. Details of these and other techniques can be found in treatises and review papers on sample digestion.

4.3.3 Methods for Flame Atomic Absorption Spectrometry

In general, digestion of solid material is always combined with dilution. Under normal conditions, when using acid digestion, 200–500 mg of biological material are usually decomposed in about 5 mL of acid, the digest being then diluted to 10–20 mL. Hence the dilution factor is about 40 for such decomposition, if not higher. Following such dilution and remembering that a technique should only be applied in its optimum working range, FAAS is suitable without reservation only for the direct determination of major components such as potassium, sodium, calcium and magnesium and minor components such as copper, iron and zinc. In some cases manganese can also be determined by FAAS in biological materials. Under given conditions it is also possible to determine aluminum, chromium, nickel and silicon. The use of the nitrous oxide–acetylene flame is a prerequisite for most of these elements to obtain correct results. Table 13 presents a number of recent applications.

For other trace elements in biological materials, the sensitivity of FAAS is generally not sufficient. For such cases, preconcentration has often been used in combination with FAAS, especially before 1980. Since today more sensitive direct methods, using for example GFAAS, are available, such preconcentration methods cannot be recommended any longer.

These classical preconcentration techniques take on a fully new dimension when they are performed automatically and on-line in a closed FI system. The most often used methods of preconcentration with such FI/FAAS

techniques for the analysis of biological materials are sorbent extraction on packed microcolumns,\(^{615–618}\) precipitation/coprecipitation\(^{619,620}\) and sorption in knotted reactors.\(^ {621,622}\) More important than high enrichment factors is the high rate of sample throughput that can be achieved with these on-line techniques, making them very suitable for FAAS. Enrichment factors of 16–40 with a sample throughput of 120–180 h\(^{-1}\)\(^ {621,623}\) appear to be much more sensible than enrichment factors of 90–180 at a sample throughput of only 13 h\(^{-1}\).\(^ {624}\) In addition, if the enrichment time is too long, the susceptibility to interferences and the risk of errors increase, such as the breakthrough of the column.

4.3.4 Methods for Graphite Furnace Atomic Absorption Spectrometry

Digests of biological materials contain about 5–50 mg of the original matrix per milliliter of solution. Since about 50% of the biological matrix is hydrocarbons, which were oxidized and removed as gases during the digestion, the remaining matrix is of the order of 2–30 mg mL\(^{-1}\). This salt content is much higher than for fresh water and the highest concentrations may reach those of seawater. This means that for those cases where the analyte concentration is low, as in seawater, the analysis of biological materials approaches the complexity of seawater analysis. For this reason, the direct analysis of biological materials has greatly benefited from the development of the STPF concept and the instrumentation associated with it. It is accepted nowadays that accurate results can be obtained for the direct analysis of many biological materials by strictly applying this concept and by excluding all forms of contamination. For example, As, Cd, Cu, Fe, Pb, Sb, Se and Zn have been determined by using platform atomization and applying Pd–Mg as modifier and B, Cr, Mn by using Mg as a modifier. The vast amount of literature in this area has been reviewed in the form of a monograph by Tsaley\(^ {565}\) covering the publications up to 1993 and by Welz and Sperling\(^{62}\) covering publications until 1997.

The number of publications on extraction techniques has decreased markedly owing to the clear advantage of the direct determination of trace elements by GFAAS with respect to simplicity, sample throughput and accuracy. The application of such techniques can be restricted to those cases where the concentration of the element is not sufficiently high for a direct determination. Pre-concentration is often required for noble metals such as gold,\(^ {625,626}\) palladium and platinum,\(^ {598,627–630}\) but also for a number of other trace elements such as beryllium,\(^ {631}\) bismuth,\(^ {632}\) cobalt\(^ {633,634}\) and nickel\(^ {635}\) under certain conditions.

Although biological materials are relatively easily dissolved or digested, direct solids analysis has frequently been described (about 150 publications during 1975–99). Problems with atomization interferences and background correction, reported in early publications since 1975, have been largely overcome by ZBC and the STPF concept. Introduction of air or oxygen during pyrolysis allows for in situ ashing and helps to avoid carbon build-up in the graphite furnace. Intercomparison studies have shown that direct solid analysis of biological materials is often able to produce accurate results, even when using only samples masses in the range 1–5 mg. When samples are properly homogenized, relative standard deviations in the range <10–20% are typical. When 5–10 subsamples are analyzed by direct solid sampling, confidence intervals for the mean result are in general within about ±10% as precise as the determination of a digest with 2–3 subsamples.

Of special interest is solid sampling for the distribution analysis of biological structures (e.g. birds feathers, human hair, special regions in organs), very small samples (e.g. insects), or for the investigation of the homogeneity

The number of publications on extraction techniques has decreased markedly owing to the clear advantage of the direct determination of trace elements by GFAAS with respect to simplicity, sample throughput and accuracy. The application of such techniques can be restricted to those cases where the concentration of the element is not sufficiently high for a direct determination. Pre-concentration is often required for noble metals such as gold, palladium and platinum, but also for a number of other trace elements such as beryllium, bismuth, cobalt and nickel under certain conditions.

Although biological materials are relatively easily dissolved or digested, direct solids analysis has frequently been described (about 150 publications during 1975–99). Problems with atomization interferences and background correction, reported in early publications since 1975, have been largely overcome by ZBC and the STPF concept. Introduction of air or oxygen during pyrolysis allows for in situ ashing and helps to avoid carbon build-up in the graphite furnace. Intercomparison studies have shown that direct solid analysis of biological materials is often able to produce accurate results, even when using only samples masses in the range 1–5 mg. When samples are properly homogenized, relative standard deviations in the range <10–20% are typical. When 5–10 subsamples are analyzed by direct solid sampling, confidence intervals for the mean result are in general within about ±10% as precise as the determination of a digest with 2–3 subsamples.

Of special interest is solid sampling for the distribution analysis of biological structures (e.g. birds feathers, human hair, special regions in organs), very small samples (e.g. insects), or for the investigation of the homogeneity
of samples. A disadvantage of solid sampling GFAAS is that not all modern furnaces allow for the introduction of solid samples and often special equipment is needed.

This and other disadvantages can be overcome by the use of suspensions of powdered samples (slurry) in a solvent such as water or dilute acid. Using an automated slurry sampler incorporating an ultrasonic probe for homogenization just prior to dispensing the sample volume into the furnace, fully automated analysis is possible with characteristics very similar to those in solution analysis. Homogenization by ultrasonic agitation is very effective, so that practically all types of biological samples can be suspended in dilute nitric acid with the addition of Triton X-100 as a wetting agent. By using a slightly wider sample capillary (0.8 mm i.d. instead of the standard 0.4 mm i.d.), particles < 600 µm can be dispensed without major problems. Table 14 gives an overview of elements determined in biological materials by either solid- or slurry-sampling GFAAS.

A complete overview of these techniques can be found in a monograph edited by Kurfürst.  

4.3.5 Methods of Speciation Analysis for Biological Materials

Being part of the biosphere, living organisms take part in the environmental cycling of elements. Owing to the metabolism of living organisms, trace elements can be present in biological materials in a large variety of chemical forms. To identify the physiologically active forms, to store and transport of species and to find sensitive indices of the status of trace elements are the main purposes of most environmental investigations into speciation in biological systems. In general, in the investigation of toxic effects, the speciation of small molecules is of concern (e.g. methylmercury), whereas in the investigation of biological functions the determination of large molecules has priority (e.g. vitamin B₁₂).

As in other areas of speciation analysis, the methods of sample collection, pretreatment and storage of biological materials for speciation studies are critical. Not only must a representative sample be collected without contamination, but also the distribution and integrity of the chemical species has to be maintained. Changes in parameters such as temperature, ionic strength, pH, pE, oxygen level, irradiation with UV light, to which the sample is exposed during and after sampling, can influence the speciation of elements. In general, it is essential to choose those analytical conditions which do not differ markedly from those found in the original system, in order to minimize such influences.

Most of the speciation studies on biological materials have been carried out with wet tissue, which is either extracted as fresh material or has previously been dissected and rapidly frozen. Extraction can be performed by blending the sample as a paste or slurry with the selected solvent or solvent mixtures using an Ultra Turrax homogenizer or ultrasonication. Other techniques, such as supercritical fluid extraction (SFE) or microwave-assisted leaching have been applied for this purpose. Using selective extraction procedures for separation, ‘first-order speciation’ is sometimes possible, especially when the number of species present is limited or when a group parameter is sufficient for the characterization. The most often performed speciation analysis of biological materials is the determination of methylmercury. However, this determination is only rarely done by using GFAAS. The most frequently described technique is extraction of methylmercury chloride or methylmercury bromide from acidic solution with toluene (e.g. fish tissue). The extract can then be analyzed directly by GFAAS after addition of dithizone or thiosulfate acting as a modifier.

The determination of inorganic and organic arsenic compounds is also of great interest. A review of methods for arsenic speciation in environmental and biological samples has been published by IUPAC. Again, since the GFAAS technique cannot be easily coupled with separation techniques such as HPLC, arsenic speciation analysis by using GFAAS has not found wide application. By using extraction with KI–toluene, the more toxic species As(III), As(V), monomethylarsenic

| Table 14 Biological matrices and elements investigated by solid-sampling and slurry-sampling GFAAS [information from the literature(2,478,636)] |
|-----------------------------------------------|-----------------------------------------------|
| Matrix                        | Elements determined by solid-sampling GFAAS | Elements determined by slurry-sampling GFAAS |
| Animal tissues                | Cd, Cs, Hg, Ni, Pb                           | B, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Se, Si, Sn   |
| Biological reference materials | Ag, As, Cd, Co, Cr, Cs, Cu, Fe, Hg, Mn, Mo, Rb, Se, Ti, Zn | Al, As, B, Ca, Cd, Co, Cr, Cu, Fe, Hg, Mg, Mn, Mo, Ni, Pb, Se, Sn, Zn |
| Human materials (hair, nails) | Ag, Al, As, Ba, Cd, Co, Cr, Cu, Fe, Hg, La, Mg, Mn, Ni, Pb, Pt, Se, Zn | Al, Ag, B, Cd, Co, Cr, Mn, Ni, Pb |
| Plant tissues                 | Cd, Co, Cu, Fe, Mg, Ni, Pb, Ti              | Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Ti, Zn     |
| Marine and aquatic samples    | As, Cr, Fe, Mn                              | As, Cd, Co, Cr, Cu, Mn, Ni, Pb, Se        |
Organotin compounds are of interest because of their toxicity. This applies in particular to tributyltin oxide, which is used as an antifouling paint. The separation of this compound from mussels and other marine organisms starts with the extraction from the homogenized tissue mixed with hydrochloric acid by using an organic solvent such as n-hexane. Mono- and dibutyltin compounds can be removed with dilute sodium hydroxide solution, and the tributyltin oxide is back extracted in nitric acid. The tin concentration in the extract is determined by GFAAS.** (543,544,641,642) Another tin compound of interest is the pesticide tricyclohexyltin hydroxide (Cyhexatin). Residues in apples can be determined directly by GFAAS after extraction with chloroform.** (643)

Bioavailable chromium has been determined in cereal products, vegetables and oil seeds by extraction with ethanol and determination by GFAAS after a digestion of the extract.** (644) When the extraction of the material alone is not selective for the species, a separation technique such as liquid chromatography (LC) has to follow. Of the LC techniques available, fractionation according to size [SEC or fast protein liquid chromatography (FPLC)] has been most frequently used.

For selenium speciation, the determination of the organic compounds and the distinction between inorganic selenite and selenate are of interest. Ion chromatography has been applied to separate selenite and selenate, and FAAS and GFAAS were used for on-line detection, depending on the required sensitivity for the analysis of feedstuffs and selenium additives in animal feeds.** (645) A greater number of inorganic and organic selenium species can be separated by coupling FPLC with GFAAS via an ultralow volume fraction collector. By using this approach for the determination of selenium species in plant tissues, a sensitivity was obtained that is comparable to that obtained by LC/ICPMS.** (646,647) Again, extraction of such Se species from the biological tissues is a critical step.** (648)

Chromium speciation, which is of great importance because of the high toxicity of Cr(VI), has not been widely applied to biological materials. Metal-free HPLC equipment and fast procedures are a prerequisite for obtaining undisturbed separation; FPLC was successfully used to separate different Cr complexes extracted from cabbage xylem.** (649) Positively charged chromium(III) species and kinetically labile complexes are not retained on the column, while the relatively stable chromium(III)–EDTA and –oxalate complexes and chromium(V) are retained and separated. Determination of chromium in the individual fractions was performed off-line by GFAAS.

For the separation of various lead species in biological materials, fractionated wash procedures using organic solvents and acids of varying strengths have been applied.** (650,651) The investigation of roots, foliage and other plant components, and the dissection of leaves into subcellular fractions with the corresponding compartmentalization of the lead content, have been described.** (651) In many cases GFAAS is used as the determination technique for the sum determination of volatile lead, that is, tetraalkyllead compounds in marine organisms.** (650)

Metallothioneins and other high molecular weight species are often determined by LC separation with various AAS detectors. A review of coupled techniques used for such analysis has been presented by Lobinski et al.** (652) The major interest is in cadmium,** (653–661) but other elements such as copper,** (655,658,661–663) zinc,** (658,661) lead,** (655) magnesium,** (663) nickel,** (661) and thallium** (660) are also determined. It is of particular interest to determine its relationship to the metal. For example, gel filtration and gel permeation chromatography are especially suitable for separating various metal-binding proteins. The determination of the metal concentrations in the eluate is carried out either by off-line coupling with FAAS or by GFAAS. Likewise for this application, the difficulty of coupling HPLC with AAS detectors is apparent. Off-line coupling with FAAS is possible when the nebulizer aspiration rate is reduced to about 2 mL min⁻¹, but the sensitivity is relatively poor.** (654,658,664) Sensitivity can be improved by using high-efficiency nebulizers for interfacing, such as the thermospray nebulizer.** (653,655,663) GFAAS offers the required sensitivity but it can only be applied off-line** (656,657) by using a fraction collector or quasi-on-line by a flow-through interface,** (537) both with limitations with respect to resolution and versatility as already mentioned (see section 4.1.5).

Other techniques which have been used in combination with AAS detection are ultrafiltration,** (665,666) ultracentrifugation** (667,668) and supercritical fluid chromatography (SFC).** (659)

Flow-injection Techniques in Environmental Analysis

J.L. Burguera and M. Burguera
University of Los Andes, Mérida, Venezuela

1 INTRODUCTION

The rapid growth in agriculture and industrial activity has resulted in chemical pollution. Industrial waste water, toxic metals, toxic organic substances, sewage sludge and soil waste materials have been discharged into the environment. The complexity of the real samples and the diversity of analytes typically encountered in environmental studies hampers the direct analysis of key components by use of a specific detection technique. To supply required data rapidly, efficiently, with the demanded accuracy and precision and with the least human attention, it would be an advantage to count on reliable and easily automatable systems.

Undoubtedly, any FI system can be considered to have a certain degree of automation mainly of the preliminary operations of the analytical process. On the other hand, it can be readily adapted to virtually every type of analytical problem, it allows direct control by the researcher and can be interfaced with a variety of possible configurations with different optical or EQ instruments typically used in routine laboratories. In this respect, FI systems have proven useful for handling contaminated complex samples and for direct pretreatment of solids and liquids with harsh chemical matrices. For these types of analytes/samples the primary advantage of FI is economic. A secondary advantage is the ease of development or refinement of method.

2 HISTORY

From the birth of FI important applications have been developed for agricultural, metallurgical, food, biological and environmental materials. Ruzicka et al. initiated the FI-spectrophotometric and potentiometric approach for the determination of phosphorus and total nitrogen content in plant materials. The same research team demonstrated for the first time the feasibility of using ion-selective electrodes for the determination of potassium, sodium and nitrate in soil extracts. The Brazilian group of Piracicaba initiated the FI-turbidimetric method (for the determination of sulfate in natural waters and plant digests) and atomic absorption spectrometry (AAS) (for the determination of calcium, magnesium and potassium in plant materials) approaches. The first two papers dealing with the determination of air pollutants (chlorine, bromine and SO2) were published by Mottola et al. based on photometric detection. Since these pioneering works were published, many books and reviews have provided an overview of the developments of FI interfaced with different kinds of detectors, highlighting the different applications in the various fields, including environmental analysis. Undoubtedly, the largest effort for the development of FI techniques for environmental analysis has been focused in the use of spectrophotometric, atomic spectrometry (AS) and some EQ detectors. The control of pollutants in waters (cationic, anionic and organic pollutants), sludges and sediments (metallic species) has received most of the...
attention, while the determination of air pollutants has been more restricted.

3 DEVELOPING METHODS FOR SAMPLE PREPARATION

The organic matter often present in environmental samples, in most cases interferes with the subsequent instrumental measurement. This serious problem can be eliminated through processes capable of converting the organic constituents into inorganic, which are free of this type of interference effect or by removing the analyte from the interfering matrix through any conventional separation technique. Transformation of the analyte into a form that can be analyzed by a specific measurement technique often requires unpleasant, tedious and time-consuming procedures such as dilution, separation, dissolution or digestion. Depending on the type of matrix, the analyte and its expected concentration in the sample and the technique to be used for measurement, one pretreatment procedure or various are to be followed. These appear to be the reason for the rather late development of FI digestion procedures followed by on-line detection of the analyte. Ultraviolet (UV), ultrasonic and microwave (MW) radiation emerged in the analytical field to dramatically improve the digestion process. Additionally, the development of on-line decomposition systems proved to be simple; they are relatively safe to use, provide a decrease in the blank values, reduce the contamination risk, are applicable to samples of different nature and are completely fit for automation. The automated procedures enable on-line coupling of the pretreatment procedures to powerful determination methods such as spectrophotometry, turbidimetry, flame atomic absorption spectrometry (FAAS), hydride generation (HG) and electrothermal atomic absorption spectrometry (ETAAS), inductively coupled plasma/atomic emission spectrometry (ICP/AES), inductively coupled plasma/mass spectrometry (ICP/MS), fluorimetry and EQ methods or to hybrid techniques such as high-pressure liquid chromatography/atomic absorption spectrometry (HPLC/AAS) or HPLC/ICP/MS, which widened the application fields to speciation studies.\(^{(19)}\)

4 MANIFOLD CONSIDERATIONS

The complete FI system would contain a sampler, the FI unit, a detector and a recording device that is capable of sample identification and evaluation of the detector signal in terms of analyte concentration. In a typical FI procedure, the entire dynamic process may take place in open tubular reactors and, therefore, a certain degree of mixing between the injectate and reagent streams is necessary before the reaction zone reaches the detector. Thus, it is necessary to emphasize the applicability of different injection modes, pumping and manifold design, which are important considerations in the field of environmental analysis. Despite the intrinsic characteristics of a given detection technique, it does not always meet the demand for specificity, sensitivity and/or selectivity for environmental analysis. The feasibility of employing in-line sample preparation further enhances the utility of FI techniques for the analysis of many samples of environmental origin, and improves the performance of the detector. In this way, (a) the reagent/analyte chemistry can be carried out under the required conditions, (b) interferents can be minimized or eliminated resulting in selectivity enhancements, (c) preconcentration of the analyte allows for lower detection limits (DLs), (d) the analyte can be placed into some detectable form and (e) speciation studies can be carried on.

The final design of a FI system is dependent on the particular requirements of the user and on the conditions defined by the method. Since sample dispersion is being used to affect specific functions, including sample dilution, mixing, reaction, preconcentration steps, etc., it should be controlled as meticulously as possible. In seeking to exploit the chemistry fully, it is desirable that manifold modifications can be made rapidly and easily to save time. In particular, the interface of the FI manifold with the detector unit must be described in detail to allow its use for routine purposes by other researchers.

5 MANIFOLD DESIGNS WITH SPECTROMETRIC DETECTORS

5.1 Spectrophotometry

The simplicity of the reactions and the ease of adaptation to continuously flowing systems enhanced the popularity of FI spectrophotometric methods for the determination of many environmentally important species, especially in water samples. The first applications were carried out with the aim of demonstrating the principles of FI techniques. Thus a number of FI manifolds have been adapted to well-known spectrophotometric methods to determine a number of anionic\(^{(20–22)}\) and cationic (calcium, iron, aluminum, lead, manganese, mercury, etc.)\(^{(22)}\) as well as organic species.\(^{(19–23)}\) With few exceptions, the manifolds are single line and permit the control of the pH and color formation, dilution of samples or preconcentration of the analyte with enhanced sensitivity and without loss of reproducibility.
Most of the spectrophotometric methods developed for the determination of sulfate are based on the removal of barium by sulfate, from its complexes with different color indicators followed by the measurement of the free ligand: methylthymol blue, dimethylsulphonazo-III or chloranilate. Barium chromate and barium chloranilate reaction columns were used as components of FI manifolds for the determination of micromounts of sulfate in sea and surface water and in rainwater samples, respectively. Other methods, indirectly determined sulfate by measuring the absorbance of thiocyanate or of the FeSO$_4^{2-}$ ion. The catalytic effect of sulfate on the reaction between zirconyl ions and methylthymol blue was also used for the indirect determination of sulfate. DLs in the range 0.1 to 0.6 mg L$^{-1}$ with relative standard deviation (RSD) below 4% but low sample throughput (up to 30 samples per hour) and narrow working range (up to 14 mg L$^{-1}$) have been achieved, although in most of these cases, removal of interfering cations by ion-exchange was necessary.

The majority of the FI procedures developed for the determination of different forms of organic and dissolved phosphorus so far are based on the complexation of orthophosphate with acidic molybdate, although strong interferences from silicates have been reported. Most of the published methods require a preliminary digestion step to convert all the phosphorus compounds present in the sample to orthophosphate. The early procedures involved hydrolysis and thermal oxidation in long digestion coils (10 m) with consequent lengthy residence times at high temperatures and elevated pressure necessary to mineralize the organic and condensed phosphates. Less drastic conditions have been used for a heated reactor containing platinum wire as catalyst in the presence of persulfate. Speciation of dissolved phosphorus in environmental samples was possible by gel-filtration in a FI manifold. UV photooxidation has been successfully used to perform in-line determination of organic phosphorus in natural waters with good sensitivity and precision. Different materials and designs of photoreactors were tested in the development of the method. Teflon photoreactors have been preferred – some of their advantages being: robustness, low cost, suitability for field applications and ease of manufacture. Samples in the range 0.1 to 4 mg P L$^{-1}$ can be analyzed at rates of 72 to 50 samples h$^{-1}$, respectively, with a DL of 0.01 mg L$^{-1}$.

An on-line MW digestion of wastewater was carried out by Haswell et al. The MW pretreatment of samples with the inorganic enzyme pyrophosphatase ensured the determination of total phosphate, as straight-chain polyphosphates and ring metaphosphates, probably present in the samples, were all converted to orthophosphate. The system design allowed all the operations, including sample injection, digestion, de-bubbling, cooling, pressure control, mixing with reagents and signal measurement to be carried out on-line in about 2 min, compared to 25 min when using traditional digestion methods. A similar, low-cost and robust FI on-line MW-induced sample digestion for total phosphorus in natural waters and wastewater has also been described in the literature. A 6 m poly(tetrafluoroethylene) (PTFE) flow-through reactor located in a domestic MW oven was used to produce the optimal oxidation and hydrolysis of the organic and condensed species suspected to be present in the real samples, with the aid of peroxodisulfate dissolved in perchloric acid. The orthophosphate formed was also detected as phosphomolydbdenum blue after on-line filtration of the digest.

Free cyanide has been spectrophotometrically determined in FI systems by slowly (over 30 min) developing the color with a buffered chloramine-T solution used as carrier, or by injecting, in a reversed-mode system, pyridine/barbituric acid reagent into the buffered chloramine-T solution. For total cyanide determination, which includes complexed cyanide, the procedure must be preceded by a tedious distillation which, if incorporated in the manifold might result in a rather complicated system with low sampling frequency. However, the combination of a fast reaction, based on the rapid formation of an unstable red intermediate product with isonicotinic acid/3-methyl-1-phenyl-2-pyrazolin-5-one, with the on-line generation and separation of hydrogen cyanide resulted in a successful system for preconcentration and sampling of total cyanide. A sampling frequency of 40 h$^{-1}$, a DL of 6 µg L$^{-1}$ and a preconcentration factor of 3.5 for a 2 mL sample have been achieved.

FI spectrophotometric methods developed so far for the determination of free chlorine in such samples are based on the formation of colored complexes with: o-tolidine (yellow), N,N-diethyl-p-phenylene diamine in phosphate buffer (pink) or 4,4’-tetramethyldiamino-thio-benzophenone (blue). Only the latest method is sensitive enough (0.2–1.0 mg L$^{-1}$) to measure free chlorine in tap water.

Another anion very often determined in water samples is chloride. The most common procedure is based on the measurement of the red-colored complex between iron(III) and thiocyanate. The amount of chloride is proportional to the absorbance measured at 480 nm. Single-line manifolds permitted the application of a simple methodology to different types of samples (surface, ground, rain or seawater and the expansion of the working range by using the stream splitting principle or performing on-line dilution. However, the sampling frequency is rather slow (up to 120 h$^{-1}$) and the precision poor (1–2%) taking into account that the sample volume was large (up to 400 µL). Better sensitivity has been achieved (0.01–10 mg L$^{-1}$) for the determination
of chloride in air and water, based on the Fe(II)/Hg-
tripryidyl-s-triazine flow system.\(^{45}\)

Although nitrogen is well known as an essential ele-
ment to life, some of its compounds (urea, ammonia, 
nitrate, nitrate, amines, etc.) could be hazardous to health 
if present in high concentrations in water supplies owing 
to their toxicity or carcinogenicity. Simultaneous determi-
nation of nitrate and nitrite is possible by controlling 
two consecutive steps: reduction of nitrate to nitrite; the 
efficiency of this reaction depends on the metal 
used, the conditioning of the column and the pH and 
diazotation, which will depend on the reagents used. 
Zinc(II), copper(II) or copperized cadmium columns 
have been used in the reduction step.\(^{46}\) The nitrite is 
diazotized with sulfanilamide and the product coupled to 
N-(1-naphthyl)ethylenediammonium dichloride to form 
an azo dye which is measured at 520 nm.\(^{47}\) A more 
sensitive method used \(p\)-aminoacetophenone for diazoti-
cation, coupled the product with \(m\)-phenylenediamine at 
pH 1.5–3.0 and measured the absorbance at 460 nm.\(^{48}\)
Many modifications and adaptations of the origi-
nal procedure have been published, all aimed to 
increase sensitivity, column lifetime, sampling rate and 
selectivity.

The commonly used methods for ammonia determi-
nation are based on the Nessler and Berthelot reaction 
in which ammonium ion is transformed into ammonia, 
separated through gas-permeable membranes and the 
gas absorbed on-line in a specific reagent and the color intensity measured at 640–800 nm.\(^{49}\)

There are several spectrophotometric methods for 
the determination of boron in environmental samples 
that require a prior separation step owing to lack of 
sensitivity.\(^{50}\) One of the most sensitive methods applied 
for the determination of boron in this type of sample is 
based on the formation of a complex with azomethine-
H using ultrasonic leaching or a time-based injector\(^{50}\) 
to avoid time-consuming sample treatment and reagent 
consumption, respectively.

Calcium in natural waters, soil extracts and plant 
digests has been spectrophotometrically determined in 
a FI system using the principle of merging zones.\(^{51}\)
Glyoxal bis (2-hydroxyanil), known as a sensitive and 
selective reagent for calcium, was used as the color-
forming reagent. Interference effects from co-existing 
elements in the matrices studied were minimized by the 
addition of triethanolamine and potassium cyanide to the 
carrier stream. A sampling rate of 180 determinations h\(^{-1}\) 
with a RSD of less than 1% have been accomplished. 
Chlorophasphonazo-III in hydrochloric acid (pH 2.2) was 
used as a chromogenic reagent for the determination 
of calcium in seawater in a FI system with a sampling 
throughput of 200 to 250 injections h\(^{-1}\) and insignificant 
effects from other alkaline-earth elements.\(^{52}\)

An indirect FI spectrophotometric method based on 
the exchange reaction between calcium and the zinc com-
plex of ethylene glycol-bis(2-aminoethylthether)tetracetic 
acid in the presence of 4-(2-pyridylazo)resorcinol has 
been described.\(^{53}\) The sampling rate was 80 samples h\(^{-1}\) 
and the results for pond and tap water samples were in 
good agreement with those obtained by FAAS.

Dissolved chromium concentrations in natural waters 
is below 1 \(\mu\)g L\(^{-1}\) and its determination is dependent 
on the preconcentration method used and changes 
between species [Cr(VI)/Cr(III)] during sampling and/or 
storage. Ion-exchange coupled on-line with the stan-
dard method based on Cr(VI) color formation with 
1,5-diphenylecarbazide is an example of a successful applica-
tion to seawater samples.\(^{54}\)

A simple FI set-up based on the absorbance of the 
orange-red iron(II)-1,10-phenanthroline complex at 
512 nm allowed the determination of iron(II) and total 
iron in a large number of waters and plant digests. How-
ever, FI systems need serious optimization procedures 
to be followed in terms of sensitivity, linearity, sampling 
rate, etc. Natural computation techniques, using jointly 
the neural network and genetic algorithms have been 
applied in the modeling and optimization of a FI manifold 
for the colorimetric determination of iron(III) in water 
samples.\(^{54}\) Thiocyanate was used as a color developing 
reagent. A comparison with AAS showed the high qual-
ity of the results. However, discrimination between Fe(II) 
and Fe(III) species has certain relevance in aquatic envi-
ronments where they are active in many redox processes. 
The Fe(III)–SCN complex was selectively retained on a 
flow cell packed with an exchange resin while the oxy-
diation of Fe(II) to Fe(III) took place in the loop of a 
previous valve.\(^{55}\) The method presents a determination 
limit of 80 \(\mu\)g L\(^{-1}\), a linear range of 80–500 \(\mu\)g L\(^{-1}\) for 
Fe(II) + Fe(III) and a precision of 5%.

Several automated FI systems have been developed for 
the photometric determination of lead after on-line col-
umn preconcentration, based on its property of forming a 
colored complex with 2-pyridylazo resorcinol,\(^{52}\) and with 
5, 10, 15, 20-tetra(4-N-sulfoethylpyridinium)porphyrin\(^{56}\) 
or the extraction with dicyclohexyl-18-crown-6 into chlo-
roform from acidic medium and addition of dithizone as 
chromogenic agent.\(^{52}\)

Eriochrome Cyanine R in the presence of cationic 
surfactants proved to be a very sensitive photometric 
reagent for the determination of aluminum in natural 
waters.\(^{57}\) A strict on-line control of the pH and 
interference effects from some concomitant species 
permitted the determination of aluminum in the range 
0.8 to 4 mg L\(^{-1}\) with a precision RSD of 0.7% at 1 mg L\(^{-1}\) 
level and a DL of 1 \(\mu\)g L\(^{-1}\).

Maximova et al. optimized an on-line preconcentration 
of some heavy metals (Pb, Co, Mn and Fe) on a capillary
column with a hydrophobic inner surface followed by MW sample processing for photometric detection in swamp water. The procedure eliminates the noise caused by the organic matrix and allows the immobilization of the photometric reagents on the sorption column.

In order to avoid costly instrumentation such as ICP/AES or AAS, a fast, automated and inexpensive screening-test for recognizing heavy-metal contamination of drinking, surface and wastewater was implemented. The test was based on the reaction of Cd, Co, Cu, Ni, Pb and Zn with dithizone at pH 6 followed by the on-line extraction of the complexes in carbon tetrachloride and photometric measurement at 500 nm.

In many environmental studies related to water quality monitoring the analysis of a large number of samples for chemical oxygen demand (COD) is often required. However, certain steps of the reactions involved prior to the spectrophotometric determination of such species are very slow. MW irradiation has been used to accelerate the oxidation of the organic matter with a potassium dichromate–sulfuric acid mixture for COD determination in natural waters. This reaction takes about 2 h in a conventional system and only a few minutes in a flow-injection microwave (FI/MW) irradiated on-line arrangement. The determinations were performed up to 100 mg L\(^{-1}\) with a precision RSD of 2.12% at 40 mg L\(^{-1}\) and a DL of 1.5 mg L\(^{-1}\).

On-line MW treatment of water samples proved successful for the reduction of urea to ammonium ions, which on reaction with NaOH release gaseous ammonia. The gas diffuses through a hydrophobic membrane and causes a pH change in a bromothymol blue indicator stream which is colorimetrically measured at 635 nm. Calibration was linear up to 45 \(\mu\)mol L\(^{-1}\) with a DL of 2.4 \(\mu\)mol L\(^{-1}\) (ten times higher than in the conventional method), a precision RSD (4%, \(n = 4\)) and a sampling rate, including sample preparation, of 14 min per sample. Although the sensitivity was worse, there are many advantages (better precision, better recoveries, rapid analysis and ease of automation) over the batch procedures.

A similar procedure, based on color change of bromothymol blue was used for the indirect determination of trimethylamine oxide in seawater at micromolar levels. The analyte was converted to the volatile trimethylamine through a titanium-mediated deoxygenating reaction; the method features a wide linear operating range (0–200 \(\mu\)mol L\(^{-1}\)) and high sensitivity with cheaper instrumentation and lower maintenance.

5.2 Turbidimetry

The turbidimetric detection of barium sulfate is almost universally used for the determination of sulfate ions in waters. The sample containing sulfate is injected in a carrier stream of barium chloride and allowed to mix in the manifold in order to form a uniform suspension. The turbidity is measured at 420 nm, but the accuracy and precision strongly depend on the crystalline form and size distribution of the precipitate particles in the suspension. Therefore, strict control of the experimental conditions must be undertaken at any time; this perfectly suits the FI concept because every standard and sample can be treated under exactly the same conditions. There are some problems associated with this procedure, namely the stability of the suspension, accumulation of precipitate on the tubing lines as well as the presence of suspended organic matter or colored components in the sample. Polyvinyl alcohol and gelatin have been used to stabilize the barium sulfate to improve the precision. The unfavorable build-up of precipitates on the transfer lines as well as their tendency to settle in the flow cell led to blocking of the manifold. Addition of hydrochloric acid to the carrier stream prevents the formation of barium carbonate, chromate, phosphate or oxalate and the alternating injection of an alkaline buffer–ethylene diamine tetraacetic acid (EDTA) solution redissolves the accumulated barium sulfate precipitate and keeps the system clean. The use of pH gradients and alkaline EDTA provided a stable suspension, which obviates the use of protective colloids. EDTA was also found useful for reducing interferences from metal ions. In order to avoid interferences from turbid samples, Van Staden incorporated in the manifold a prevailve filtration accessory consisting of a packed activated carbon tube or an active carbon filter paper. The incorporation of an anion exchange resin in a FI manifold permitted the preconcentration of sulfate for its sensitive turbidimetric determination in water.

A silver nitrate turbidimetric procedure has been applied to the determination of chloride in river water in a single-line flow system. The turbidity of silver chloride suspensions formed in nitric acid is measured at 440 nm in the range 0 to 14 mg L\(^{-1}\) with a sampling rate of only 15 h\(^{-1}\).

5.3 Atomic Spectrometry

Initial reports dealt with the use of the FI system as a mere alternative to manual introduction for FAAS. In such systems, the noise problems associated with the air bubbles in segmented sample insertion systems are eliminated, the analyst can use sample volumes in the microlitre range per measurement, and the sample flow rate is optimized to allow higher atomization with a net increase in sample analysis throughput. Olsen et al. determined cadmium, copper, lead and zinc in polluted seawater at the part per million level at a
rate of 180–250 samples per hour; however, the sampling frequency depended on the preconcentration required. They developed an on-line FI preconcentration method using a microcolumn of Chelex-100 resin, allowing the determination of lead at concentrations as low as 10 µg L\(^{-1}\) and 1 µg L\(^{-1}\) for cadmium and zinc.

Martínez-Jiménez et al.\(^{(73)}\) have developed a continuous precipitation and filtration flow system coupled on-line with the atomic absorption spectrometer. This technique allows the quantitative separation and preconcentration (by a factor of 700) of trace amounts of lead from tap water samples. Ammonia is used as a precipitating reagent and no collector was required. Several calibration graphs suited to the degree of enrichment proposed for the determination of lead(II) in the range 1.2–1500 µg L\(^{-1}\).

On-line coprecipitation–preconcentration systems can also greatly improve the DLs down to 0.23, 3.2 and 1.4 µg L\(^{-1}\) for determination of metal species such as cadmium, lead and nickel, respectively, in various water samples and soils. The analytes are precipitated and collected on the inner wall of a knotted reactor with diethylidithiocarbamate-copper(II) and eluted with isobutyl methyl ketone.\(^{(74)}\)

The advantages of FI solvent extraction coupled with AAS include high preconcentration factors, improved nebulization efficiency, reduced reagent consumption and the reduction of laboratory waste.\(^{(75)}\) Gallego et al.\(^{(76)}\) reported the indirect determination of anionic surfactants with an automatic continuous liquid–liquid extractor. The method involves the formation of the detergent-[1,10-phenanthroline-copper(II)] ion pair and extraction into methyl isobutyl ketone. The overall concentration can be determined indirectly by measurement of copper present in the organic layer by AAS. A phase separator fitted with a PTFE porous membrane was specially designed for the determination of detergents in the concentration range 0.1–5.0 µg mL\(^{-1}\).

Ma et al.\(^{(77)}\) described a FI on-line sorbent extraction system to determine cadmium, copper and lead in digest solutions of environmental samples using octadecyl functional groups (C\(_{18}\)) bonded silica gel as sorbent with diethylammonium-N,N-diethylidithiocarbamate or ammonium diethylidithiophosphate as complexing agent and methanol as eluent. DLs were 0.8, 1.4 and 10.0 µg L\(^{-1}\) respectively for cadmium, copper and lead. These elements were determined in coal fly ash, calcareous loam soil and lake and estuarine sediments.

Interesting work presented by Bysouth et al.\(^{(78)}\) used masking agents in the determination of lead in tap water by FAAS with FI preconcentration. The selectivity of immobilized 8-hydroxyquinoline for lead was improved by the use of masking agents during preconcentration, prior to its determination. Interference by iron, copper, aluminum and zinc is suppressed by including triethanolamine, thiourea, fluoride, acetylatedone or cyanide in the buffer as masking agents. On the other hand, Sperling et al.\(^{(79)}\) determined chromium(III) and chromium(VI) in fresh water samples using on-line preconcentration with selective adsorption on activated alumina. Linear calibration for both species was established over the concentration range 10–200 µg L\(^{-1}\) with DLs of 1.0 and 0.8 µg L\(^{-1}\) for Cr(III) and Cr(VI) respectively.

The research team of Perkin-Elmer at Uberlingen has introduced some routine applications of on-line ion-exchange preconcentration systems for AS.\(^{(12)}\) In particular, enrichment factors from 25 to 31 were obtained for copper, cadmium and lead from natural and sea water samples by FI coupled with AAS. Conical ion-exchange columns were found to be superior to uniform diameter columns in reducing dispersion during elution so that higher enrichment factors could be achieved using smaller sample volumes (1.6 mL per determination). The system can be easily also adaptable to an ICP spectrometric system.

FI sample introduction for ETAAS systems is less straightforward than FAAS or hydride generation atomic absorption spectrometry (HGAAS) owing to the discontinuity of ETAAS operation, this obviously being the cause of the slower development of the related techniques.\(^{(16)}\) Historically, the main obstacles for efficiently and harmoniously combining FI on-line with ETAAS have been overcome by the research groups of the Department of Applied Research of Perkin-Elmer in Uberlingen and Mérida, Venezuela.\(^{(16,80)}\) FI and ETAAS by on-line column preconcentration of metal species (such as: As, Pb, Cd, Co, Cu, Fe, Ni and Zn) from natural and seawater samples, has provided further impetus to the development in this field. Various sample introduction modes have been proposed by different workers. The conventional off-line mode is performed using pipettes for the deposition of the concentrate into the furnace after its pretreatment and collection in small vials. With on-line systems, the concentrates are dispensed automatically into the furnace by a pump via a sampling probe. FI also proved to be an efficient interface to ETAAS for: (1) sample deposition in the furnace by hydride sequencing, thermospray and high pressure nebulization; (2) selective sorbent extraction.\(^{(91)}\)

Without any question, ICP at its current stage is the analytical technique that provides the most adequate simultaneous multielement analysis capacity. ICP allows the simultaneous assay of several elements at major, minor, trace and ultratrace levels without changing any experimental parameter in aqueous or organic solvents. However, the formation of polyatomic ions (particularly below m/z = 80) can cause serious interferences. Such
species can be introduced via precursor atoms in atmospheric gases, with the sample matrix or impurities in the argon support gas, and cause a systematic error. The first applications of FI/ICP can be traced in the review published by Christian and Ruzic in 1987. Up to then, FI was used as an adjunct of conventional ICP instruments, which had bulky nebulizers. Therefore, FI systems are coupled to ICP or to ICP/MS for: (1) the on-line removal of matrix interferences, (2) trace enrichment of analytes, (3) on-line dilution and (4) on-line sample digestion procedures. In this context, trace metals in seawater, sewage sludge and natural waters have been determined with good precision and accuracy. The introduction of samples by capillary gas chromatography allowed the speciation and determination (down to 0.1 ng L$^{-1}$) of organotin compounds in river-water samples.

Tsavle et al. have initiated the on-line MW sample pretreatment for the determination of Hg in water. A reaction coil and a ballast-load coil are placed and oriented vertically within the cavity and chimney of a focused MW oven in a manner that provides a reliable long-term operation with increased reaction and irradiation times. Samples are mixed in a “batch” with an appropriate oxidation reagent and loaded on an autosampler. Thereafter, all further operations are performed automatically within 90–402 s (depending on the sample volume and the instrument program used for a given determination). When the amalgamation accessory was used, a PTFE filter holder with a PTFE micropore membrane filter was placed between the gas–liquid separator and the quartz absorption cell to avoid aerosol droplets entering the amalgamation accessory. The limits of detection were 0.01 and 0.2 µg L$^{-1}$ for mercury, with and without amalgamation, respectively.

A technical note reports on the evaluation of a Perkin-Elmer flow-injection mercury system (FIMS) for the determination of Hg in sewage sludge, sediment and soil samples. The DLs were as low as 53 µg L$^{-1}$ for sample volumes of 500 µL and RSD of 2% (n = 3) at 10 µg L$^{-1}$ Hg level. The same approach has been successfully tested for the determination of total mercury in environmental samples using MW digestion coupled to FIMS.

A similar system was described by Lamble and Hill for the determination of total mercury in environmental solid samples. The slurried samples were injected into a carrier of hydrochloric acid and brominated mixture before passing through the coil situated in the MW cavity. After mixing with hydroxylammonium chloride to remove excess bromine, mercury was determined in an on-line generation system. Each sample was processed in 50 s with a DL of 15 ng L$^{-1}$.

Morales-Rubio et al. have described a two-line system for the determination of mercury in environmental materials (sewage sludge, polluted farmland soil and lake sediment) using on-line MW digestion and atomic fluorescence spectrometry (AFS) as detector. The acidified slurry samples (400 µL) were injected and carried through the PTFE digestion coil (4 m) located inside the oven (at 10% power level) for 50 s and through an ice/water bath. The reductant stream merged with the digest and mixed in a reduction coil before entry to the gas liquid separator. This system allowed accurate determination of mercury in certified environmental reference materials with a precision ranging between 0.5 and 1.5% RSD, a DL of 0.09 ng g$^{-1}$ and a throughput of 15 samples per hour.

Another interesting approach has been developed for the determination of total arsenic in geothermal water samples. An appropriate volume of sample (0.1–2.0 mL) mixed with acids (H$_2$SO$_4$ and HNO$_3$) and an oxidizing agent (K$_2$S$_2$O$_8$) is subjected to MW heating. The cooled digest was mixed with a reductant (KI and ascorbic acid) and sodium borohydride to form volatile arsenic which was detected by FAAS in a quartz cell. The method allowed the determination of total arsenic with a DL of 0.2 ng of arsenic, a precision RSD of 2.5–4.5% and recovery values in the range 101–102%.

López-Gozález et al. have described an on-line HPLC/MW oxidation-HGAAS four channel system for the selective determination of arsenite, arsenate, dimethylarsinate (DMA), monomethylarsonate (MMA), arsenobetaine (AsB) and arsnocholine (AsC) in environmental samples (mineral water, sewage water, harbor seawater, synthetic fish extract and sediment extract). Samples and multistandard solutions were injected into an anionic cartridge leading to a 100 µL sample loop, placed before an HPLC anionic column. Arsenite, arsenate, MMA and DMA were quantitatively retained in the anionic cartridge while AsB and AsC passed through it into the sample loop and separated in the chromatographic column. The column effluent mixed with the oxidizing solution flowed to the digestion coil in the oven for decomposition. The digest was cooled in an ice-bath and a T-junction was used to acidify the sample. In a second T-junction the digested sample was mixed with the reductant and the separated volatile arsenic entered the quartz atomization cell. The anionic species can be separated and determined by removing the anionic cartridge from the system and introducing water instead of the oxidizing agent. After optimization of the chromatographic and MW-oxidation parameters, the RSD was 3–5% with DLs between 0.3 and 0.9 ng for all species (for 100 µL sample volume) and conversion efficiency close to 100% in all cases.

Le et al. also speculated arsenic except that they used a dual system to avoid removal of the cartridge during the procedure. Comparable resolution was obtained by using HPLC-separation/MW-digestion with HGAAS or...
ICP/MS detection. Complete separation of five arsenicals was achieved on a reversed-phase C_{18} column by using sodium heptanesulfonate as ion pair reagent and the DLs were for example 10 µg L^{-1} for arsenite, DMA and AsB, 15 µg L^{-1} for MMA and 20 µg L^{-1} for arsenate.

An automatic and on-line cryogenic trapping system and MW heating was used for the determination and speciation of arsenic in aqueous samples by FI/HGAAS using sodium tetrahydroborate as reductor.\(^{(98)}\) The separation of the species was based on a pH selective procedure: arsine from As(III) alone was generated in the presence of citric acid while nitric acid was used to generate the corresponding arsines from total inorganic arsenic, MMA and DMA. These were cryogenically trapped in a PTFE coil knotted and sealed inside another wider diameter tube located in the oven and through which liquid nitrogen was suctioned by negative pressure. Based on their different dielectric constants, the arsines were selectively liberated by using a heating cycle of MW radiation with volatilization times of 90, 180 and 235 s for dimethylarsine, monomethylarsonane and arsine, respectively. The DLs were in the range 20 to 60 ng As for 10 mL sample volume, with the possibility of improving it by increasing sample size or running several consecutive reactions.

5.4 Luminescence

The first applications of FI coupled with chemiluminescence (CL) detection were reviewed by Burguera et al. in 1982.\(^{(99)}\) Up to then, some metal species, tertiary amines, hydrogen peroxide and sulfite\(^{(100)}\) were the species of environmental interest which were determined in natural waters. This initial trend has almost been followed up to date, but using different CL reactions, e.g. (1) the determination of tertiary amines in water and seawater over the range 1 \times 10^{-5}–1 \times 10^{-2} mol L^{-1} based on the oxidation of the analyte by sodium hypochlorite in presence of Rhodamine B as a sensitizer;\(^{(101)}\) (2) the determination of aqueous ozone for potable water treatment;\(^{(102)}\) (3) the determination of a nonionic surfactant in aqueous environmental samples;\(^{(103)}\) (4) the determination of ultratrace concentrations of nitrite in water;\(^{(104)}\) (5) the simultaneous determination of nitrate and nitrite in water by gas-phase CL.\(^{(105)}\) One interesting application of FI is the in situ shipboard determination of species such as hydrogen peroxide,\(^{(106)}\) copper and manganese using CL reactions.\(^{(107,108)}\)

The analytical signals are dramatically affected by environmental conditions such as ionic strength, pH and interferents which can be stabilized in a FI system. The advantage of using FI for fluorescence-based measurements is that reproducibility can be significantly improved.\(^{(109)}\) FI sample processing has been used for the determination of: 0–10^{-5} mol L^{-1} total primary amines in seawater,\(^{(109)}\) 0.2–300 ng mL^{-1} copper(II) in natural waters;\(^{(111)}\) 10^{-8}–10^{-4} mol L^{-1} of residual peroxides in water;\(^{(112,113)}\) and µmol L^{-1} levels of sulfur species (sulfite, sulfide and methanethiol) in fogwaters\(^{(114)}\) with good reproducibility, precision and rapidity using the o-phthalaldehyde/mercapto-ethanol, 2,2’-dipyridylketone hydrazone/hydrogen peroxide, p-hydroxyphenylacetate/peroxide/peroxidase and N-acridinylmaleimide/N,N-dimethylformamide reactions, respectively.

6 MANIFOLD DESIGNS WITH ELECTROCHEMICAL DETECTORS

The use of EQ methods in environmental analysis depends on the availability of instrumentation, trained personnel and practical procedures for complex matrixes. They are suitable for on-line field applications although EQ detection suffers from memory effects and electrostatic interferences. The design of flow-through EQ detectors for on-line couplings needs special consideration. Some novel sensors have been tried, including wall-coated (or open) tubular, packed bed (or porous) tubular, wire, cascade, wall-jet and thin layer designs. They monitor anionic species such as chloride, bromide, cyanide, nitrate and ammonium and to a lesser extent toxic metals, such as Pb, Hg, Cd, Cu, Zn and Ni, which substantially contribute to the pollution of land and water, and are readily determined by spectroscopic methods.

6.1 Amperometry

An amperometric flow-through detector was used for the determination of cyanide in different kinds of surface and groundwaters\(^{(115)}\) by injecting the sample into an alkaline electrolytic carrier stream with good precision (2%) and high sampling frequency (100 h^{-1}).

Arsenic was determined in contaminated soil samples by a novel technique based on gas diffusion through porous membranes.\(^{(116)}\) Arsine generated in a donor stream of sodium borohydride passes quickly across a membrane into an acceptor stream of sulfuric acid, and the resulting solution is carried to a flow-through amperometric cell equipped with a dual gold electrode and Ag/AgCl as reference electrode. The detector provided enhanced selectivity, high sensitivity and low DL and affords the possibility of the development of field instrumentation for on-site determinations. A closed loop FI system was used for the determination of sulfur dioxide in air samples.\(^{(117)}\) The manifold permitted the direct intercalation of air samples into a carrier solution containing the complex Fe(III)-1,10-phenanthroline as a regenerable chemical form. The extent of reduction of the complex to ferroin at the gas/liquid interface was
amperometrically monitored with an Ag/AgCl–carbon-paste electrode system. The composition and mode of preparation of the paste was found to considerably affect the performance of the system. The analyte was determined in the range 0.3–14.0 ppm (v/v) with RSD of about 3% at a rate of 25 samples per hour.

### 6.2 Ion-selective Electrodes

A home-made coated tubular solid-state chloride selective electrode was used by Van Staden to determine chloride up to 5000 mg L\(^{-1}\) with a precision of less than 1.7%.\(^\text{118}\) The drawback of this procedure was the strong interference from mercury(II) ions. A similar approach was manufactured for the determination of inorganic bromide in soil in the range 1–5000 mg L\(^{-1}\), at a rate of 80 samples per hour and with a standard deviation (SD) of 1.6%.\(^\text{119}\)

Okumoto et al. interfaced a flow system with a gas-diffusion separator and a cyanide-selective electrode to screen wastes from metal plating processes.\(^\text{120}\) They claimed a DL of 0.1 mg cyanide L\(^{-1}\) and a sampling frequency of 40 h\(^{-1}\).

Improved DLs, compared to spectrophotometric methods, have been reported for the potentiometric determination of ammonium in seawater using a liquid-membrane ammonium-sensitive electrode\(^\text{121}\) or a gas diffusion/dialyser unit.\(^\text{35}\) On-line preconcentration on ion-exchange microcolumns and incorporation of gas-diffusion units proved successful but the final choice will depend on the particular analytical requirement.

### 6.3 Voltammetry

Voltammetric techniques, in particular absorptive cathodic stripping voltammetry are suitable for trace metal determination and speciation as they combine high sensitivity with speciation capabilities. Their combination with FI techniques facilitates in situ monitoring of various species in environmental samples.\(^\text{122}\) For this purpose, a flow-through cell (4 µL) mounted in an automated voltammetric system monitored traces of cobalt in uncontaminated seawater.\(^\text{123}\) A hanging mercury drop was used as electrode, while the chloride present in the seawater was the counter-ion for the Ag/AgCl reference electrode. The cell was combined with on-line UV digestion, on-line de-oxygenation and on-line standard addition for on-board determination of cobalt distribution in coastal waters.

Traces of metals can also be determined using chemically modified electrodes designed to enable both, preconcentration (binding) and surface interaction for subsequent quantification of the analyte accumulated on the surface. Carbon-paste electrodes for instance, are simple to prepare and have an easily adjustable fresh surface, which is generated in a reproducible manner. Such an electrode, modified with 1,2-bismethyl(2-amino cyclopentene-carboxyhydrate)ethane was incorporated in a flow system for the preconcentration and determination of copper in water.\(^\text{124}\) As little as 1.4 × 10\(^{-6}\) mol L\(^{-1}\) of Cu(II) can be determined in water with a precision of 2.9% for a preconcentration time of 4 min. Cu, Pb, Cd and Hg were determined in seawater, speciated as total particulate, particulate sorbed to inorganic matter, total dissolved and labile by differential pulse anodic stripping voltammetry.\(^\text{125}\) The total-particulate-containing filters were MW digested and the organic matter in water samples was destroyed by UV photolysis. The elements in the filtered water were on-line pre-concentrated on a Chelamine microcolumn, eluted and determined by the EQ method and also by FAAS (Cu, Pb and Cd) or cold vapor atomic absorption spectrometry (CVAAS) (Hg) for quality control (QC).

### 7 DETERMINATION OF POLLUTANTS IN ENVIRONMENTAL SAMPLES

The main development in FI environmental analysis have been highlighted in the following reviews:

1982 Water pollutants.\(^\text{99}\)
1985 Cations, anions, COD, halogens, sulfur dioxide, organic and other polluting species determination.\(^\text{19,126}\)
1987 Anions determination.\(^\text{11,14,20}\)
1988 Environmental samples.\(^\text{1}\)
1989 Environmental samples.\(^\text{8,10}\)
1990 Cations and anions and other polluting species determination.\(^\text{15,127}\)
1991 Water quality monitoring.\(^\text{21,128,132}\)
1994 Different pollutants in water.\(^\text{23,129,130}\)
1995 Cations and anions determination in different kinds of samples.\(^\text{12}\)
1996 Soil pollutants.\(^\text{131}\)
1997 Different polluting species determination in different kinds of samples.\(^\text{180}\)
1998 Different polluting species determination in different kinds of samples.\(^\text{133}\)

### 8 THE PRESENT AND THE FUTURE

At present FI provides simple, handy, automable and versatile instrumentation which makes it suitable to meet the requirements of any laboratory wanting to make this type of analysis. The volume of papers involving the
analysis of water is substantial, and in a more restricted way the determination of different air and soil pollutants is well documented.

As realization spreads that the determination of the “total” concentration of an analyte is insufficient to yield an overall measure of toxicity, continued concern over environmental pollution will be reflected in the development and optimization of multielemental and speciation studies with imaginative FI setups. Analysis of biological materials as biomonitors of environmental pollution, airborne particulate, soils and waters will become of interest with on-line sample pretreatment, analyte separation from the matrix and preconcentration techniques to improve the sensitivity for the determination of individual species of the material under study.

1 Introduction

1 INTRODUCTION

Formaldehyde (HCHO) is a ubiquitous component of both the remote atmosphere and polluted urban atmospheres. This, together with the uniqueness of the chemistry it is involved in, make it a particularly important compound. Interest in ambient concentrations of formaldehyde derives both from concerns over health effects and from the primary role that formaldehyde plays in the tropospheric chemistry cycle. Formaldehyde is unique in that it acts as a funnel through which much of the carbon flux passes during the course of oxidation to CO and CO₂. In spite of the increasing interest in the levels and fate of aldehydes and other carbonyl compounds in the environment, there is at present no simple method available for the determination of trace amounts (i.e. nanograms) of carbonyls in air, water, and other environmental samples. In the field of atmospheric chemistry alone, measurements of parts per billion (ppb) levels of carbonyls in ambient air or simulated atmospheres ("smog chamber studies") are critical to the development of a better understanding of hydrocarbon photochemistry, oxidant formation and removal processes including scavenging by precipitation, and atmospheric aerosols. Specifically, accurate formaldehyde measurements are important in constraining and validating photochemical models of the troposphere. Other important areas requiring measurement of trace levels of carbonyls in air include source and near-source sampling (engine exhausts, industrial emissions, etc.), and health related studies (e.g. indoor pollution, workplace environments etc.), all of which have important regulatory implications. In addition, formaldehyde is listed as a carcinogen or suspected carcinogen and its workplace exposure needs to be monitored.

Typical concentrations observed range from 0.5 ppb in remote areas to 75 ppb during severe air pollution episodes in urban areas. In the late 1960s formaldehyde levels greater than 120 ppbv were observed by unambiguous spectroscopic techniques FTIR in polluted areas.

Formaldehyde is a ubiquitous component of both the remote atmosphere and polluted urban atmospheres. Interest in ambient concentrations of formaldehyde derives both from concerns over health effects and from the primary role that formaldehyde plays in the tropospheric chemistry cycle. It is an important intermediate product occurring in all regions of the atmosphere, and arises from the oxidation of methane and other biogenic and anthropogenic hydrocarbons. In spite of the increasing interest in the levels and fate of formaldehyde in the environment, there is at present no simple method available for the determination of trace amounts (i.e. nanograms) of carbonyls in air, water, and other environmental samples. This
near Los Angeles. Between 1980 and 1985 the few data available show that the average concentrations in major cities were between 3 and 16 ppbv with maxima as high as 68 ppbv in Downey, California.\(^{(6)}\) Average concentrations for the more remote Colorado mountains are around 1 ppbv during the summer and fall months,\(^{(8)}\) while values between 50 and 500 pptv have been recorded for the Mauna Loa Observatory, Hawaii.\(^{(9,10)}\)

About 24 million metric tons (Mt) of 37% formaldehyde solution are produced worldwide per year, of which 4.2 million Mt are in North America, 6.2 million Mt are in Europe and 6.3 million Mt are in Asia.\(^{(11)}\) The end-uses of formaldehyde in the USA and in Europe are shown in Figure 1. The formaldehyde solution is incorporated into urea–formaldehyde and phenol–formaldehyde resins, which are widely used in industry for the production of foam insulation, particle board and plywood.\(^{(12)}\) The particularly simple structure of formaldehyde results in extreme reactivity. Formaldehyde and ammonia yield methenamine, or hexamethylene tetramine, which is used as a urinary antiseptic. Nitration of methenamine gives the explosive cyclonit, also known as research development explosive (RDX). Formaldehyde reacts in the presence of Ca(OH)\(_2\) to give pentaerythritol, the tetrani-trate of which is the explosive pentaerythritol tetranitrate (PETN). The ready reaction of formaldehyde with protein leads to its use in the tanning industry and in treating various vegetable proteins to render them fibrous. The reactivity with proteins is also the basis for the use of formaldehyde as a disinfectant and embalming agent and as a soil sterilant.

Formaldehyde is an important intermediate product occurring in all regions of the atmosphere, and arises from the oxidation of methane and other biogenic and anthropogenic hydrocarbons. Formaldehyde serves both as a major source of the hydroperoxyl radical (HO\(_2^*\)) and as a means of sequestering the hydroxyl radical (\(^*\)OH) in the form of HO\(_2\). Formaldehyde is also a major source of carbon monoxide in air masses not influenced by anthropogenic sources. In the troposphere, where the concentration of methane is considerably higher than that of non-methane hydrocarbons (NMHCs), methane becomes the dominant formaldehyde precursor. At the earth’s surface, local sources of NMHCs also become important in producing formaldehyde. Formaldehyde is generated from the oxidation of biogenic hydrocarbons such as isoprene and the terpenes.\(^{(13–15)}\) Formalde-hyde is also anthropogenically generated directly from incomplete combustion processes and through secondary processes.\(^{(16)}\) The predominant source of urban formaldehyde is believed to be the photooxidation of many hydrocarbons that are present in the atmosphere.\(^{(17)}\) In rural areas of dense vegetation biogenic sources are often the predominant precursor. For example, isoprene oxidation (indicated by reactions with either OH or O\(_3\)) efficiently forms formaldehyde along with several other key atmospheric species.

Many foundries use furan resins as binding agents for sand, resulting in emissions of phenol, furfuryl alcohol and formaldehyde. In indoor environments, formaldehyde is emitted in substantial amounts as phenol and urea resins are incorporated into foam insulation, plywood and particle board. Growing concerns over the toxicity and the resultant properties of formaldehyde has created a significant demand for new methods to monitor exposures.

The use of titrimetric methods to measure formaldehyde concentrations is widespread for industrial hygiene applications and source measurements but the methods are not sensitive enough for ambient analysis. With colorimetric methods formaldehyde is converted into a chromogen by the addition of such compounds as chromotropic acid, pararosaniline, acetylacetone or 3-methyl-2-benzothiazolone hydrazone (MBTH) and the amount of chromogen is measured spectrophotometrically. They are among the earliest known of the refined versions,\(^{(18)}\) are reasonably sensitive, have low detection limits and can be automated\(^{(19)}\) but color development is relatively slow and sensitivity is limited.

Most of the present techniques for sampling atmospheric formaldehyde involve running a stream of atmospheric air through either a liquid or a solid sorbent. As the air passes through the sorbent it is scrubbed free of aldehydes. Liquid sorbents are normally placed in a small vessel called an impinger. Impingers must normally be

![Figure 1](image-url)

**Figure 1** End-uses of formaldehyde: (a) United States, 1997 total 4.2 million Mt, (b) Europe, 1997 total 6.2 million Mt.\(^{(11)}\) MDI, methane diphenyl di-isocyanate.
refrigerated if they are to be operated for long periods of time, otherwise the media will evaporate. The most common liquid medium for trapping formaldehyde is water. Solid sorbents alone do not have a high collection efficiency unless they are coated with a scavenger compound such as acidified 2,4-dinitrophenylhydrazine (DNPH), 2-hydroxymethylpiperidine or N-benzylene-ethanolamine. Low sampling rates of 1–1.5 L min⁻¹ of air must be used, with typical sampling times of 20 min or several hours. Thus determinations of low concentrations of formaldehyde require rather long sampling times followed by rather slow laboratory analysis.

Chromatographic methods, including ion chromatography (IC) as formate, gas chromatography (GC), and high-performance liquid chromatography (HPLC), have been used for formaldehyde analysis. Direct analysis in urban air using GC has been less successful due to poor sensitivity. However, derivatization of formaldehyde either in the sampling device or immediately after collection has improved stability of samples and allows quantitation of low levels of formaldehyde. GC of oxazolidine or the dinitrophenyl hydrazone derivative and especially HPLC of the DNPH derivative has been shown to provide adequate sensitivity. Capillary GC has also been used.

to analyze formaldehyde derivatives. Several of these methods suffer from stability problems and the need for expensive and specialized equipment for analysis. Faster real-time measurements are possible with spectroscopic methods. Spectroscopic techniques have included differential ultraviolet (UV) absorption, FTIR, and TDLAS. These techniques generally employ long atmospheric paths or use multiple pass cells to attain adequate sensitivity. Sawicki et al. studied a very large number of spectrometric methods for formaldehyde analysis and concluded that spectrofluorimetric determination with 2,4-pentanediene should be the method of choice when sensitivity, specificity and mild reaction conditions are desired.

Current techniques employed in measuring ambient formaldehyde concentrations include TDLAS, continuous scrubbing fluorimetric detection (CSFD), DNPH derivatization techniques employing cartridges and coils, FTIR, and differential optical absorption spectroscopy (DOAS). The first three classes of techniques were compared at a rural location in North Carolina in a study published by Kleindienst et al. and again in the Los Angeles basin by Lawson et al. (this study also included FTIR and DOAS measurements). In relatively clean rural air (5–15 ppbv) all methods appear to provide reasonably good agreement to within approximately 35%. Table 1 shows different methods used for the estimation of formaldehyde for different matrices with respect to sensitivity and interferences.

2 PROPERTIES

2.1 Physical Properties

Formaldehyde (methanal) is a gas (bp −21 °C). Monomeric formaldehyde gas is characterized by a pungent odor and is extremely irritating to the mucous membrane of the eye, nose and throat even when present in concentrations as low as 20 ppm. Formaldehyde is handled either as an aqueous solution (formalin) or as one of the solid polymers paraformaldehyde ((HCHO)2) or trioxane ((CH2O)3). It is extremely soluble in water.

Monomeric formaldehyde is available commercially only in solutions stabilized with methanol. In most cases, these are aqueous solution with methanol contents ranging from 1 to 15%.

2.2 Chemical Properties

The chemical properties of formaldehyde are given in Table 2.

3 METHODS OF MANUFACTURE

Formaldehyde is prepared industrially in three different ways. The first method involves the dehydrogenation of methanol. Methanol vapors are passed over a heated silver catalyst at 300 °C, as shown in Scheme 1.

\[
\text{CH}_3\text{OH \xrightarrow{\text{Ag, 300°C}} HCHO + H_2O}
\]

Scheme 1

In the second method methanol is oxidized in air. Methanol vapors and a limited amount of air are passed...
over a heated silver catalyst at 450°C, as shown in Scheme 2. In this method, the condensate obtained is a mixture of formaldehyde, methanol and water. The excess methanol is removed by distillation and the resulting mixture is known as formalin (40% HCHO, 8% CH₃OH and 52% H₂O).

\[ 2\text{CH}_3\text{OH} + O_2 \xrightarrow{\text{Ag, 450°C}} 2\text{HCHO} + 2\text{H}_2\text{O} \]

**Scheme 2**

Thirdly methane or propane–butane mixtures (from natural gas) can be oxidized in the presence of various metallic oxides, as shown in Scheme 3.

\[ \text{CH}_4 + \text{O}_2 \xrightarrow{\text{metallic oxides}} \text{HCHO} + \text{H}_2\text{O} \]

**Scheme 3**

4 **USES**

Formaldehyde is a powerful disinfectant and antiseptic and is used for preserving anatomical specimens. Its main uses are in making plastics. Formaldehyde is condensed with urea and phenols to make plastics, with ammonia to give hexamethylenetetramine, a urinary antiseptic, and is also used to make RDX. Formaldehyde binds to the amino group of proteins, thus rendering toxic proteins harmless, but does not change their immunological properties. This is the basis for the production of the polio vaccine, and the tetanus and diphtheria toxoids.

5 **EXTRACTION OF FORMALDEHYDE FROM DIFFERENT MATRICES**

5.1 Air

Formaldehyde can be sampled from air using bubblers, impingers, mist chambers, sorbent cartridges, etc., in different media. The more commonly used media include water, MBTH, and chromotropic acid. Details of specific sampling methods are covered in the appropriate section.

5.2 Rainwater/Drinking Water/Wastewater

These samples can be analyzed directly by any colorimetric or chromatographic method.

5.3 Toothpaste

1 g of the paste is dissolved in 5 mL of 0.1 N NaOH diluted to 100 mL with distilled water. An aliquot is used to estimate the formaldehyde concentration.

5.4 Tablet

The tablet is weighed and 200 mL water is added. The solution is refluxed for 30 min, then the condenser is cooled and rinsed out. The solution is diluted to 500 mL and filtered. An aliquot of the filtrate is used to estimate the formaldehyde concentration.

5.5 Formal

The sample is dissolved in water and is diluted to a volume such that the equivalence of formaldehyde is approximately 0.05 mg mL⁻¹. This solution is used to estimate the formaldehyde concentration.

5.6 Crystalline Formal

The sample (20–40 mg) is dissolved in 1 : 2 H₂SO₄ and is diluted to 1 L. The solution is heated and incubated for 2 h and then cooled. An aliquot of the solution is used to estimate the formaldehyde concentration.

5.7 Cellulose

The sample (0.1 g) is added to 100 mL of 1 : 2 H₂SO₄. The solution is sealed and incubated at 90°C for 2 h and then cooled. An aliquot of the solution is used for estimation.

5.8 Milk

Milk samples can be analyzed directly using any colorimetric method or any standard technique.

5.9 Urine

A few drops of 50% NaOH solution are added to the sample to precipitate the phosphate, and the mixture is then shaken well and filtered. An aliquot of the solution is used to estimate the formaldehyde concentration.

6 **ANALYSIS**

6.1 Qualitative Analysis (Snell\(^{(42)}\))

6.1.2 Derivatives

6.1.2.1 Methylene Bismethone A few drops of a 5–10% solution of methone or dimedon (dimethyl dihydro resorcinol), and 5,5-dimethylcyclohexanediene in ethanol are added to the sample which has been made slightly acidic with acetic acid. A precipitate of methylene bismethone is formed, and recrystallized from methanol and water (mp 189 °C).

6.1.2.2 Formaldehyde p-nitrophenyl Hydrazone

A few drops of p-nitrophenyl hydrazine hydrochloride in mildly acidic ethanol are added to a solution containing formaldehyde. A precipitate of formaldehyde p-nitrophenyl hydrazone is formed, and recrystallized from ethanol (mp 181–182 °C).

6.1.2.3 Formaldehyde 2,4-dinitrophenyl hydrazone

A few drops of 2,4-DNPH hydrochloride in mildly acidified ethanol are added to a solution containing formaldehyde. A precipitate of formaldehyde 2,4-dinitrophenyl hydrazone is formed, and recrystallized from ethanol (mp 166–167 °C).

6.1.2.4 Methylene Dinaphthol

A few drops of a formaldehyde-containing solution are treated with 33% alcohol, β-naphthol and a little hydrochloride. A precipitate of methylene dinaphthol is formed. On gently boiling small white needles are formed, which turn brown at 180 °C, and melt with decomposition to a brownish-red liquid at 189–192 °C.

6.2 Quantitative Analysis

6.2.1 Titrimetric Methods

Titrimetric methods, because of their simplicity and accuracy, are widely employed for the determination of formaldehyde concentration when present as a major component. However, there is a limit for aldehyde concentration below which it is inadvisable to expect great accuracy. An assessment of these methods has been carried out by Buchi,43 and by Reynolds and Irwin.35 Reynolds and Irwin35 reviewed the different titrimetric methods available and concluded that for measuring small quantities of pure formaldehyde, the iodimetric method is most suitable. The potassium cyanide method is the best volumetric method for the estimation of formaldehyde concentration in the presence of acetone, acetaldehyde, benzaldehyde, higher aldehydes and ketones. The sodium sulfite method is very simple and adaptable to field tests. The hydroxylamine hydrochloride method has the disadvantage of being insufficiently sensitive for low concentrations and is rather slow, requiring several hours for completion. For colored solutions the pH titration method has a distinct advantage, but it is no better than ordinary titration in the case of colorless solutions.

6.2.1.1 Sodium Sulfite Method

**Principle.** When formaldehyde reacts with sodium sulfite, it forms the formaldehyde bisulfite addition product, and sodium hydroxide is liberated quantitatively according to Scheme 4.

\[
\text{CH}_2\text{O} + \text{Na}_2\text{SO}_3 + \text{H}_2\text{O} \rightarrow \text{NaOH} + \text{CH}_3(\text{Na}_2\text{SO}_3)\text{OH}
\]

**Scheme 4**

The amount of base produced is determined titrimetrically.

**Reagents.** The following reagents are used: (a) Na$_2$SO$_3$ (125 g of anhydrous sodium sulfite or 250 g of hydrated sodium sulfite is dissolved in water and diluted to 1 L); (b) 0.25 N H$_2$SO$_4$.

**Procedure.** To 100 mL sodium sulfite solution in an Erlenmeyer flask, W g (about 2 g) of the sample is added and the mixture is swirled to effect complete reaction. Then 3–5 drops of 1% ethanolic thymolphthalein indicator solution are added and the solution is titrated with 0.25 N H$_2$SO$_4$ to the colorless end-point. A blank determination is also carried out.

**Calculation.**

\[
\text{HCHO (wt\%)} = \frac{(A - B)(N)(MW)(100)}{(W)(1000)}
\]
where \( A \) = volume of sulfuric acid solution required for sample titration (mL), \( B \) = volume of sulfuric acid solution required for blank titration (mL), \( N \) = normality of the sulfuric acid solution, \( MW \) = molecular weight of formaldehyde (30.03 g) and \( W \) = sample weight (g).

### 6.2.1.2 Alkaline Peroxide Method

**Principle.** Formaldehyde is oxidized with \( \text{H}_2\text{O}_2 \) in the presence of excess base according to Scheme 5.

\[
2\text{HCOONa} + 2\text{H}_2\text{O} + \text{H}_2\text{O}_2 \rightarrow 2\text{HCOONa} + 2\text{H}_2\text{O} + \text{H}_2
\]

**Scheme 5**

Excess \( \text{NaOH} \) is determined by titration with standard acid.

**Interferences.** Acetone (less than 7 wt%) and acetaldehyde (less than 0.5 wt%) do not interfere.\(^{(43)}\)

**Reagents.** The following reagents are used: (a) 1 N \( \text{NaOH} \); (b) neutral \( \text{H}_2\text{O}_2 \) (10 mL of 30\% \( \text{H}_2\text{O}_2 \) is neutralized with 1 N \( \text{NaOH} \) using bromothymol blue as an indicator and diluted to 100 mL); (c) 1 N \( \text{H}_2\text{SO}_4 \).

**Procedure.** Water (10 mL) is placed in a stoppered 250 mL Erlenmeyer flask and weighed, then 3 mL of sample is added and the flask is weighed again. To this 50 mL of 1 N \( \text{NaOH} \) solution is added and then immediately but slowly 50 mL of neutral \( \text{H}_2\text{O}_2 \) solution is added. The mixture is heated on a water bath for 15 min, while shaking cautiously with a general rotatory motion. It is cooled to room temperature with cold water. The excess \( \text{NaOH} \) is titrated with 1 N \( \text{H}_2\text{SO}_4 \) using 2–3 drops of bromothymol blue as indicator to a bluish-green endpoint. A blank determination is also made.

**Calculation.**

\[
\text{HCHO (wt\%)} = \frac{(B - A)(N)(MW)(100)}{(W)(1000)}
\]

where \( A \) = volume of sulfuric acid solution required for sample titration (mL), \( B \) = volume of sulfuric acid solution required for blank titration (mL), \( N \) = normality of the sulfuric acid solution, \( MW \) = molecular weight of formaldehyde (30.03 g), and \( W \) = sample weight (g).

### 6.2.1.3 Iodimetric Method

**Principle.** The reaction of formaldehyde with hypoiodite reagent serves as a method for determination, according to Scheme 6.

\[
\text{HCHO} + \text{NaOI} + \text{NaOH} \rightarrow \text{HCOONa} + \text{NaI} + \text{H}_2\text{O}
\]

**Scheme 6**

In acidic media iodide self-oxidizes into iodine, as shown in Scheme 7.

\[
4\text{I}^- + \text{O}_2 + 4\text{H}^+ \rightarrow 2\text{I}_2 + \text{H}_2\text{O}
\]

**Scheme 7**

Many other aldehydes and ketones also react with the iodine reagent and the method described is basically useful only with known systems. The recovery of formaldehyde is approximately 98.5\%.

**Interferences.** The interference of methanol, a known constituent in commercial formaldehyde solutions, has been disputed. This iodimetric method is particularly useful for the determination of small concentrations of formaldehyde in aqueous solution.

**Reagents.** The following reagents are used: (a) 3 N \( \text{NaOH} \); (b) 0.2 N \( \text{NaOI} \); (c) 0.1 N \( \text{Na}_2\text{S}_2\text{O}_3 \); (d) \( \text{H}_2\text{SO}_4 \).

**Procedure.** A sample containing up to 0.16 g of formaldehyde is weighed into an iodine flask and diluted with water to about 100 mL. Then 30 mL of 3 N sodium hydroxide solution and 75 mL of 0.2 N sodium hypoiodite are added and the flask is stoppered. The mixture is allowed to stand at room temperature for 30 min. Approximately 95 mL of \( \text{H}_2\text{SO}_4 \) is added and the liberated iodine is titrated immediately with 0.1 N sodium thiosulfate solution using starch indicator. At least one blank determination is carried out with each set of samples.

**Calculation.**

\[
\text{HCHO (wt\%)} = \frac{(B - A)(N)(MW)(100)}{(W)(1000)}
\]

where \( A \) = volume of sodium thiosulfate solution required for sample titration (mL), \( B \) = volume of sodium thiosulfate solution required for blank titration (mL), \( N \) = normality of the sodium thiosulfate solution, \( MW \) = molecular weight of formaldehyde (30.03 g), and \( W \) = sample weight (g).

### 6.2.1.4 Potassium Cyanide Method

**Principle.** Formaldehyde reacts with potassium cyanide, unreacted cyanide is converted into silver cyanide by the addition of a measured amount of standard silver nitrate solution and excess silver nitrate is determined by titration with thiocyanate as shown in Schemes 8 and 9.

\[
\text{HCHO} + \text{KCN} \rightarrow \text{CH}_2(\text{OK})\text{CN}
\]

**Scheme 8**
Reagents. The following reagents are used: (a) 0.1 N KCN; (b) 0.1 N AgNO₃; (c) 0.1 N KCNS.

Procedure. A sample containing approximately 0.15–0.25 g of dissolved formaldehyde is weighed and added to a 200 mL glass-stoppered Erlenmeyer flask containing 100 mL of 0.1 N KCN. After shaking, the mixture is washed into a volumetric flask with 40 mL of 0.1 N AgNO₃ and 10 mL of 1:9 nitric acid. The volume is made up to 200 mL. The solution is filtered and 100 mL of the filtrate is titrated with 0.1 N KCNS solution using ferric alum as an indicator.

Calculation.

\[
\text{HCHO (wt\%)} = \frac{(100 - (40 - 2A))(N)(MW)(100)}{W(1000)}
\]

where \(A\) = volume of thiocyanate solution required for titration (mL), \(N\) = normality of the thiocyanate solution, \(MW\) = molecular weight of formaldehyde (30.03 g) and \(W\) = sample weight (g).

6.2.1.5 Ammonium Chloride Method

Principle. The reaction is shown in Scheme 10.

\[
6\text{HCHO} + 4\text{NH}_3 \rightarrow (\text{CH}_2)_{6}\text{N}_4 + 6\text{H}_2\text{O}
\]

This reaction is the basis for a quantitative determination, with the excess ammonia being determined by steam distillation or by titration. Buchi\(^{(43)}\) modified the technique for the use of neutral NH₄Cl.

Interferences. Ethanol and acetone have no significant effect on the analysis, but acetaldehyde in concentrations higher than 5% leads to high values.

Reagents. The following reagents are used: (a) 1 N NaOH; (b) neutral NH₄Cl; (c) 1 N HCl.

Procedure. A 6 g sample of approximately 37% formaldehyde solution is weighed into a 100 mL flask and diluted to the volume of the flask. Then 25 mL of this solution is added to an Erlenmeyer flask together with 3 drops of 0.1% bromothymol blue indicator and neutralized with NaOH solution until the indicator color changes to blue. Neutral NH₄Cl (1.5 g) and NaOH solution (25 mL) are added rapidly, the flask is closed tightly using silicon grease to ensure a perfect seal and the reaction mixture is allowed to stand for 1.5 h.

The excess NH₃ is titrated with HCl until the color changes to green. A blank determination is also carried out.

Calculation.

\[
\text{HCHO (wt\%)} = \frac{(B - A)(N)(180.2)(100)}{W(1000)}
\]

where \(A\) = volume of hydrochloric acid required for sample titration (mL), \(B\) = volume of hydrochloric acid required for blank titration (mL), \(N\) = normality of hydrochloric acid and \(W\) = sample weight (g).

6.2.1.6 Mercurimetric Method

Principle. The reaction is shown in Scheme 11.

\[
\text{K}_3\text{HgI}_4 + \text{HCHO} + 3\text{NaOH} \rightarrow \text{Hg} + \text{HCOONa} + 2\text{KI} + 2\text{NaI} + 2\text{H}_2\text{O}
\]

The precipitated Hg is determined iodimetrically.

Interferences. Organic hydroperoxide and acetaldehyde in concentrations as low as 0.5% can cause interference. Acetone and methyl and ethyl alcohols have no appreciable effect.

Reagents. The following reagents are used: (a) mercuric chloride; (b) KI solution; (c) 2 N NaOH; (d) 2 N acetic acid; (e) 0.1 N iodine solution; (f) 0.1 N sodium thiosulfate.

Procedure. A 1.75 g sample of 37% formaldehyde solution or its equivalent is weighed into a 500-mL volumetric flask and diluted to the volume of the flask. A 25-mL portion of this solution is added to a 200-mL glass-stoppered Erlenmeyer flask, containing a solution of 1 g of mercuric chloride and 2.5 mL of KI in 35 mL of water. Then 20 mL of 2 N NaOH is added. The mixture is shaken vigorously for 5 min then acidified with 25 mL of 2 N acetic acid. Immediately 25 mL of 0.1 N iodine solution is added and the mixture is agitated until the precipitate is completely dissolved. The excess iodine is back-titrated with 0.1 N sodium thiosulfate solution using starch solution as the indicator. A blank determination is also carried out.

Calculation.

\[
\text{HCHO (wt\%)} = \frac{(B - A)(N)(MW)(100)}{W(2)(1000)}
\]

where \(B\) = volume of sodium thiosulfate solution required for blank titration (mL), \(A\) = volume of sodium thiosulfate solution required for sample titration (mL), \(N\) = normality of the sodium thiosulfate solution,
where

\[ MW = \text{molecular weight of formaldehyde} \ (30.03 \text{ g}) \] and
\[ W = \text{sample weight (g) in 25 mL}. \]

6.2.1.7 Hydroxylamine Method The hydroxylamine method is widely used for the determination of carbonyl compounds in the presence of alkaline-sensitive products and impurities, such as phenol, cresol and resinous materials. Formaldehyde reacts with hydroxylamine hydrochloride forming an oxime and liberating hydrochloric acid as shown in Scheme 12. Using a suitable acid–base indicator (or preferably by pH titration when the solutions are colored) the reaction can serve as a basis for quantitative estimation.

\[
\text{HCHO + H}_2\text{NOH-HCl} \rightarrow \text{HCN=NOH + HCl + H}_2\text{O}
\]

**Scheme 12**

Reagents. The following reagents are used: (a) hydroxylamine hydrochloride; (b) 0.1 N sodium hydroxide.

Procedure. To 10 mL 1 N hydroxylamine hydrochloride solution in an Erlenmeyer flask, W g (about 2 g) of sample is added and agitated. After agitation, the mixed solutions are neutralized with 0.1 N sodium hydroxide solution using methyl orange as indicator. It is essential to match the end-point (which is red to orange and not yellow) against a blank. The method is reported as being sensitive to 0.1 mg of formaldehyde. A blank determination is also carried out.

Calculation.

\[
\text{HCHO (wt%)} = \frac{(A - B)(N)(MW)(100)}{W(1000)}
\]

where \( A \) = volume of sodium hydroxide solution required for sample titration (mL), \( B \) = volume of sodium hydroxide solution required for blank titration (mL), \( N \) = normality of sodium hydroxide solution, \( MW \) = molecular weight of formaldehyde (30.03 g) and \( W \) = sample weight (g).

6.2.2 Colorimetric Methods

Absorption spectrophotometry forms the basis for many of the aldehyde monitoring techniques. The chromotropic acid method is used widely and is approved protocol for the measurement of formaldehyde.\(^{44,45}\) The method is specific for formaldehyde but is not very sensitive. Another commonly used colorimetric method utilizes pararosaniline as the chromogen since it gives an enhancement in the sensitivity by approximately a factor of 2 over the chromotropic acid method. However, the technique is prone to interference from carbonyl compounds and other low-molecular-weight aldehydes. The modified pararosaniline method\(^{18}\) is not affected by phenol: formaldehyde ratios ranging from 1 to 100, whereas such ratios cause total inhibition of the chromotropic acid method. Miksch et al.\(^{18}\) concluded that the modified pararosaniline method was more sensitive, more reproducible and easier to use than the chromotropic acid method. Another important method uses MBTH for formaldehyde measurement. This method’s sensitivity has been reported as 30 ppb formaldehyde based on a sampled air volume of 25 L in 35 mL of absorbing solution. Several other colorimetric methods for formaldehyde have also been reported. These include the 7-amino-5-hydroxy-2-naphthalene sulfamic acid and the \( p \)-phenylenediamine methods.

To perform large numbers of analyses or for semicontinuous analysis of water or air, colorimetric analyses can be adapted for use with autoanalyzers. Autoanalyzers are usually implemented by one of two methods: either continuous or discrete (batch). In a continuous flow analysis, samples are analyzed from a flowing stream with any necessary operations (such as filtering and reagent addition) performed prior to the measurement of chemical and physical properties. Actual determinations are made using flow-through sample cells. In discrete analysis, samples are placed in individual containers for the duration of the analysis. Preliminary operations of dilution, reagent addition and mixing are performed on each sample at different locations within the analyzer. Each treated sample is then presented in sequence to the sensing device. A batch of samples is usually preloaded for processing by this technique. While both techniques are used in process control and laboratory analyses, continuous analysis is more often utilized in automated process control applications because of its faster response time.\(^{46}\)

All the colorimetric methods covered here relate to formaldehyde analysis in air and require specific sampling methods, although these methods could also be used directly for estimation of formaldehyde in solutions.

6.2.2.1 Chromotropic Acid Method

**Principle.** Formaldehyde reacts with chromotropic acid (1,8-dihydroxynaphthalene 3,6-disulfonic acid) in concentrated sulfuric acid solution to form a purple colored dye, which is determined spectrophotometrically at 580 nm. The formaldehyde may be collected either in water, in aqueous bisulfite or directly in the chromotropic acid–sulfuric acid solution. By collecting in water 0.1–2.0 µg mL\(^{-1}\) formaldehyde can be measured. This corresponds to a minimum detectable quantity of 0.1 ppm in a 40-L air sample collected in 20 mL water. The sensitivity can be increased 10-fold by sampling directly into the chromotropic acid–sulfuric acid solution. The reproducibility of the method is within ±5%.\(^{47}\)
Interferences. The chromotropic acid method has very little interference from other aldehydes (<0.01% from saturated aldehydes and a few percent from acrolein). Alcohols, phenols, aromatic hydrocarbons and olefins all show negative interference but the concentrations of these classes of compounds in ambient air are too low to lead to serious errors.

Apparatus. Two coarse-fritted bubblers in series are used to collect the samples. A pump capable of maintaining a metered flow of 1 L min$^{-1}$ through the sampling train for up to 24 h is required.

Reagents. The following reagents are used: (a) chromotropic acid reagent (0.10 g of chromotropic acid disodium salt is dissolved in water and diluted to 10 mL, filtered if necessary and stored in the dark. Fresh solution is made weekly); (b) concentrated H$_2$SO$_4$ (specific gravity = 1.86); (c) stock formaldehyde solution (1 mg mL$^{-1}$) (2.7 mL of 37% formalin solution is diluted to 1 L with distilled water. This solution is standardized by the addition of excess sodium bisulfite to an aliquot of the solution, followed by iodimetric titration of the formaldehyde bisulfite addition product after the excess bisulfite has been oxidized by I$_2$. Alternatively, sodium formaldehyde bisulfite can be used as a primary standard, in which case 4.470 g of formaldehyde bisulfite is dissolved in distilled water and diluted to 1 L. This solution is stable for at least three months); (d) dilute standard formaldehyde solution (10 µg mL$^{-1}$) (1 mL of standard stock solution is diluted to 100 mL with distilled water. Fresh solution is prepared daily).

Procedure. Distilled water (20 mL) is placed in each bubbler, and the sampling train is connected and aspirated at 1 L min$^{-1}$ for a suitable time to collect enough formaldehyde for analysis (24 h). The collection efficiency in a single bubbler is approximately 80%, i.e. 95% of the formaldehyde is trapped using two bubblers. After sampling, the volume is adjusted to 20 mL and a 4-mL aliquot of the sample is pipetted to the stoppered test tube. A blank is also prepared using 4 mL distilled water. A 0.1 mL portion of 1% chromotropic acid solution is added and mixed, then 6 mL concentrated sulfuric acid is cautiously added from a pipette. The solution is allowed to cool and the absorbance is read at 580 nm in a 1-cm cell. The amount of formaldehyde present in each aliquot taken is determined from the calibration curve obtained as described next.

Calibration. A freshly prepared standard formaldehyde solution (10 µg formaldehyde mL$^{-1}$) is used to prepare the calibration solution. Different amounts (0, 0.1, 0.3, 0.5, 0.7, 1.0 and 2.0 mL) of this solution are pipetted into a series of glass-stoppered graduated tubes. Each sample is diluted to 4 mL with distilled water and the color is developed as described above. The absorbance is plotted against formaldehyde concentration (µg mL$^{-1}$). The air concentration of formaldehyde is calculated as follows:

$$\text{ppm (volume)} = \frac{\text{total HCHO(µg)}}{\text{VM}} \times 24.47$$

where total formaldehyde is the sum of the amounts collected in each bubbler, V is the volume of air sampled (at 101,325 kPa and 25 °C) and M is the molecular weight of formaldehyde (30.03 g).

6.2.2.2 3-Methyl-2-benzothiazole Hydrazone Method

Principle. The formaldehyde in ambient air is collected in a 0.05% aqueous solution of 3-methyl 2-benzothiazolone hydrazone hydrochloride. The resulting azine is then oxidized by ferric chloride/sulfamic acid solution to form a blue cationic dye in acid solution which can be measured at 628 nm after 12 min (Figure 2). The concentration of total aldehydes is calculated in terms of formaldehyde, and formaldehyde in the range 0.03–0.7 µg mL$^{-1}$ can be measured. This corresponds to a minimum detectable concentration of 0.03 ppm in a 25-L air sample. The reproducibility of the method is within ±5%.$^{(7)}$

Apparatus. The samples are collected in all-glass bubblers with a coarse fritted inlet. It is normally necessary to sample ambient air for quite long periods to obtain sufficient aldehyde for analysis and a pump capable of drawing at least 0.5 L min$^{-1}$ for 24 h is required. A critical orifice, a rotameter or a gas meter can be used to meter the flow.

Figure 2 Sequence of reactions involved in the MBTH method. A = 3-methyl-2-benzothiazolone hydrazone, B = azine, C = reactive cation, D = blue cationic dye. (Reprinted with permission from Sawicki et al.$^{(26)}$ Copyright 1961 American Chemical Society.)
Reagents. The following reagents are used: (a) MBTH (0.05%) (0.5 g of MBTH is dissolved in distilled water and diluted to 1 L). The reagent becomes turbid either on storage or during sampling. If this occurs, it is filtered by gravity. The solution is stable for a week or more if stored in the cold in a dark bottle; (b) oxidizing reagent (1.6 g sulfamic acid and 1.0 g ferric chloride is dissolved in distilled water and diluted to 1 L); (c) stock formaldehyde solutions (1.0 mg mL$^{-1}$, prepared as in chromotropic acid method); (d) dilute standard formaldehyde solution (10 µg mL$^{-1}$, prepared as in chromotropic acid method).

Procedure. A measured volume of ambient air at a rate of 0.5 L min$^{-1}$ is sampled through 35 mL of MBTH solution in the absorber until sufficient aldehyde for analysis has been collected. An average collection efficiency of 84% has been determined for sampling under these conditions although higher efficiencies have been reported for slightly modified conditions. The efficiency is between 90 and 95% using 10 mL of 0.2% aqueous MBTH in a bubbler aspirated at 1 L min$^{-1}$.

After sampling the volume of absorbing reagent solution is made up to exactly 35 mL with distilled water (to compensate for evaporation losses) and allowed to stand for 1 h. Then 10 mL of the sample solution is pipetted into a glass-stoppered tube and an equal volume of reagent is pipetted into a second tube to serve as a blank. A 2 mL portion of oxidizing solution is added to each tube and mixed well. After allowing to stand for at least 12 min the absorbance of the sample is read at 628 nm against the reagent blank in 1-cm cells. The aldehyde content (expressed as µg formaldehyde mL$^{-1}$) is determined from the calibration plot prepared as described.

Calibration. Freshly prepared dilute standard formaldehyde solution is used to calibrate this method. Different amounts (0, 0.5, 1.0, 3.0, 5.0 and 7.0 mL) of this solution are pipetted into a series of 100 mL volumetric flasks and diluted to the volume of the flask with 0.05% MBTH solution. After allowing to stand for 1 h, 10 mL aliquots of each of these solutions are transferred to stoppered test tubes. Oxidizing solution (2 mL) is added and mixed well. After 12 min the absorbance of each solution is determined at 628 nm against the blank in 1-cm cells. Absorbance is plotted against µg formaldehyde per mL of solution. The air concentration of total aliphatic aldehydes (as formaldehyde) is given by:

$$\text{ppm (volume)} = \frac{\mu g \text{ mL}^{-1} \text{HCHO} \times 35 \times 24.45}{VME}$$

where $V =$ volume of air sampled (at 101.325 kPa and 25 °C), $M$ is molecular weight of formaldehyde (30.03 g) and $E$ is the collection efficiency of the bubbler which can be estimated by using two bubblers in series. If a coarse-fritted bubbler is used, $E$ may be taken to be 0.84%.

6.2.2.3 Nash Method

Principle. Formaldehyde reacts with ammonium acetate, acetic acid and acetylacetone (Nash reagent) and forms the blue compound diacetyldihydrolutidine. The detection limit and precision of the method are 0.05 µg mL$^{-1}$ and 1.43%, respectively.

Apparatus. A mist chamber, filter holder, pump and rotameter/gas meter are required.

Reagents. The following reagents are used: (a) Nash reagent (75 g of ammonium acetate, 1.5 mL acetic acid, and 1.0 mL acetylacetone are placed in a volumetric flask and made up to 500 mL with distilled water); (b) stock formaldehyde solution (as described for chromotropic acid method); (c) standard formaldehyde solution (as described for chromotropic acid method).

Procedure. Formaldehyde is sampled using the mist chamber technique. The air is first passed through a 1.2-µm pore size poly(tetrafluoroethylene) (PTFE) filter to remove particles and then exposed to a fine spray of deionized water (25 mL) with a flow rate of 12 L min$^{-1}$. After sampling, the volume of absorbing reagent solution is made up to exactly 25 mL with distilled water (to compensate for evaporation losses). Then 5 mL of Nash reagent and 5 mL of sample solution are placed in a test tube. After allowing to stand for at least 10 min, the absorbance of the sample is determined at 412 nm against the reagent blank (water) in a 1-cm cell. Formaldehyde can be determined from the calibration plot prepared as described next.

Calibration. A freshly prepared, dilute standard formaldehyde solution containing 10 µg formaldehyde mL$^{-1}$ is used to prepare calibration solutions. Different amounts (0, 2, 4, 6 and 8 mL) of this solution are added into a series of 10 mL volumetric flasks and diluted to the volume of the flask with water. A 5-mL aliquot of each solution is transferred to a stoppered test tube and 5 mL of Nash reagent is added and mixed well. After 10 min the absorbance of each solution is determined at 412 nm against the blank in 1-cm cells. The absorbance is plotted against µg formaldehyde mL$^{-1}$ of solution.

6.2.2.4 Modified Pararosaniline Method

Principle. Acid-bleached pararosaniline and formaldehyde lead to the formation of intensely colored pararosaniline methyl sulfonic acid which is read at
570 nm (Figure 3). The reproducibility of the slope is 0.52 ± 0.37 mL⁻¹.

Only low-molecular-weight aldehydes give positive interferences, and only when present in a large excess compared with formaldehyde. Negative interferences could be caused by compounds that react with either pararosaniline or formaldehyde. Cyanide, sulfite and hydroxylamine all form stable, well-characterized adducts with formaldehyde.¹⁸

Reagents. The reagents used are formaldehyde stock solution, pararosaniline solution and sodium sulfite. Details are given below. Methanol-free formaldehyde solutions are prepared by refluxing approximately 20 g of paraformaldehyde in water, filtering the solution and diluting to 1 L. The solution is standardized by adding the formaldehyde solution to a 1 M solution of sodium sulfite to quantitatively produce sodium formaldehyde bisulfite and hydroxyl ions. It is back-titrated to its original pH using 1.0 M HCl to determine the amount of formaldehyde added. The stock solution is stable for several months.

Pararosaniline (0.16 g) is dissolved in 20 mL of concentrated HCl and the mixture is diluted to 100 mL with deionized water. This reagent remains stable for several months when stored in an amber bottle.

Sodium sulfite (8 mM) is prepared by dissolving 0.10 g of anhydrous sodium sulfite in deionized water and
diluting the solution to 100 mL with deionized water. It is prepared daily.

**Procedure.** A 2.5-mL sample of formaldehyde solution is placed in a cuvette and 250 µL of acidified pararosaniline reagent is added. After mixing thoroughly, 250 µL of the sodium sulfite reagent is added. The cuvette is capped and placed in a water bath at 25°C. The color is allowed to develop for 60 min and read at 570 nm. The blank and the sample are read against deionized water.

**Calibration.** Freshly prepared standard formaldehyde solution (0.06 mg mL⁻¹), is used to calibrate this method. Different amounts (0, 0.5, 1.0, 3.0, 5.0 and 7.0 mL) of this solution are pipetted into cuvettes and 250 µL of acidified pararosaniline reagent is added. After mixing thoroughly, 250 µL of the sodium sulfite reagent is added. The cuvettes are capped and placed in a water bath at 25°C. The color is allowed to develop for 60 min and read at 570 nm. The blank and the sample are read against deionized water.

**6.2.3 Polarographic Method**

The polarographic technique has gained favor as a practical method for the determination of formaldehyde and other aldehydes. The increase in popularity of the polarographic technique may be attributed to improved electrode design and automated microprocessor-based differential pulse polarography. A pulse technique that is capable of good signal-to-noise ratios employs the pulse train shown in Figure 4. The formaldehyde–hydrazone derivative could be determined in acetate buffer solution by differential pulse polarography. An aliquot of the derivatized solution is then analyzed by differential pulse polarography with a dropping mercury electrode.

**6.2.3.1 Principle**

Polarography involves the study of current–voltage relationships at a dropping mercury electrode under certain controlled conditions. It consists in electrolyzing a solution of an electroactive substance between a dropping mercury electrode functioning as a cathode, and some reference electrode (a pool of mercury) which acts as an anode. The area of the anode is correspondingly large so that it may be regarded as incapable of becoming polarized and the potential of such an electrode remains fairly constant. A potential is applied between these electrodes and increased in a

1.1 and an intercept of

Figure 5 shows the polarographic cell and a basic circuit
for obtaining a polarogram.
A steep rise in the current is observed, which continues
to rise with increasing potential until it reaches a
maximum value when the concentration of ions at the
electrode surface approaches zero. Now the current no
longer increases with applied potential but approaches a
steady limiting value. The particle reduced at the mercury
surface diffuses away from the surface either by forming
an amalgam with the mercury, which subsequently
detaches from the capillary top or by simply diffusing
back into the bulk of the solution.
Septon and Ku
have described a method for polaro-
determination of formaldehyde in air samples.
This polarographic method is free from interferences
from acetaldehyde, acrolein and benzaldehyde as their
potential differences are different from that of formalde-
yde. Therefore, this technique can be used to moni-
tor formaldehyde where incomplete combustion occurs
since it is possible to resolve formaldehyde from other
aldehydes. Septon and Ku
determined the collection
efficiency by connecting two sampling devices in series.
The efficiency was determined from the amount of vapor
that passed through the first bubbler and was absorbed in
the backup. The efficiency was 98.6 ± 0.3% for six sam-
ple s when 10 ppm formaldehyde was collected at a flow
rate of 1 L min
1 for 30 min in a bubbler containing 10%
methanol–water solution.

This method was validated by generating samples with
concentration of 5.8–17.7 mg m
The pooled coefficient of variation or relative stan-
dard was 0.08. A linear regression of formaldehyde taken
as a primary standard); concentrated (98%) sulfuric acid;
0.1 N sulfuric acid (standardized against sodium carbonate
solution); and 12.5% (w/v) sodium sulfite.

Standardization of formaldehyde stock solutions
involves weighing 50 ± 0.5 g of formaldehyde solution
and transferring it to a 250-mL beaker, then adding 25 mL
of 12.5% w/v sodium sulfite (whose pH is adjusted to 9.6
with 0.1 N H2SO4) and titrating to pH 9.6 with 0.1 N
H2SO4. The concentration of formaldehyde (in ppm) is
calculated as follows:

Formaldehyde (ppm) = \frac{(A - B)(C)(D)}{E}

where \( A \) = sulfuric acid solution required to titrate the
sample (mL), \( B \) = sulfuric acid solution required to
titrate the blank (mL), \( C \) = normality of the sulfuric
acid solution (mequiv mL
1), \( D \) = (30 mg mequiv
1 of
HCHO) \( \times \) (1000 µg mg
1) or 30 \( \times \) 10³ µg mequiv
1 of
formaldehyde, and \( E \) = amount of sample used (g).

6.2.3.4 Sample Preparation
The total volume of each sample is measured and recorded and the volume is made
up with 10% methanol. Then 5 mL of the sample solution, 4 mL of acetate buffer and 1 mL of 2% hydrazine reagent
are added to the polarographic cell.

6.2.3.5 Analysis
All glassware and polarographic
cells are soaked in 6 M nitric acid, rinsed thoroughly

stepwise manner. At first only a small current flows (the
so-called residual current), and this continues until the
decomposition of the reducible ionic species is reached.

The maximum value when the concentration of ions at the
electrode surface approaches zero. Now the current no
longer increases with applied potential but approaches a
steady limiting value. The particle reduced at the mercury
surface diffuses away from the surface either by forming
an amalgam with the mercury, which subsequently
detaches from the capillary top or by simply diffusing
back into the bulk of the solution.

Septon and Ku
251
have described a method for polaro-
graphic determination of formaldehyde in air samples.
This polarographic method is free from interferences
from acetaldehyde, acrolein and benzaldehyde as their
potential differences are different from that of formalde-
yde. Therefore, this technique can be used to moni-
tor formaldehyde where incomplete combustion occurs
since it is possible to resolve formaldehyde from other
aldehydes. Septon and Ku
251
251
determined the collection
efficiency by connecting two sampling devices in series.
The efficiency was determined from the amount of vapor
that passed through the first bubbler and was absorbed in
the backup. The efficiency was 98.6 ± 0.3% for six sam-
ple s when 10 ppm formaldehyde was collected at a flow
rate of 1 L min
1 for 30 min in a bubbler containing 10%
methanol–water solution.

This method was validated by generating samples with
concentration of 5.8–17.7 mg m
3. Average recovery was
103%. The pooled coefficient of variation or relative stan-
dard was 0.08. A linear regression of formaldehyde taken
vs formaldehyde found showed correlation with a slope
of 1.1 and an intercept of \(-1.4 \text{ mg m}^{-3}\). The quantitative
determination limit is 50 ppb, and the relative standard
deviation of replicate determinations at this level was 0.04.

6.2.3.2 Sampling
Air (30 L) is sampled in 10% v/v
methanol/deionized water in a bubbler connected to a
sampling pump at a flow rate of 0.5–1 L min
1. A prefitter
of mixed cellulose acetate membrane (0.8-µm pore size
and 37 mm diameter) with a 37 mm polystyrene filter
holder is used. The maximum volume sampled should not
exceed 160 L at 1 L min
1. The bubbler is connected to the
sampling pump with rubber tubing (poly(vinyl chloride)
(PVC) tubing should not be used before the bubbler). If
evaporation losses occur during the sampling, additional
solution is added to the bubbler to maintain the required
concentration of methanol solution. With each batch of
ten samples at least one blank is subjected to the same
handling except that no air is drawn through it. The
bubbler solution is transferred to a 20-mL glass vial.

6.2.3.3 Reagents
Details of reagents to be used are
as follows. Methanol solution (10% v/v) is prepared
by diluting 100 mL of reagent grade methanol to 1 L
with deionized water. The acetate buffer (pH 4) is an
equimolar mixture of acetic acid and sodium acetate
(0.1 M) in deionized water. For the hydrazine reagent
(2% w/v) 2 g of hydrazine sulfate (\( \text{H}_2\text{NNH}_2 \cdot \text{H}_2\text{SO}_4 \))
is dissolved in deionized water and diluted to 100 mL
with deionized water. It is prepared fresh every week and
kept tightly closed. The supporting electrolyte is prepared
by mixing 10% methanol solution, acetate buffer and 2%
hydrazine reagent in a ratio of 5 : 4 : 1, respectively. A 100-
ml portion of this solution is required for each analysis
and is prepared fresh daily. The formaldehyde stock
solution (1000 ppm) is prepared by dissolving 2.7 g (about
3 mL) of 37% formaldehyde solution in 1 L of deionized
water. The solution is stable for 3 months. Appropriate
serial dilutions of the formaldehyde stock solution are
made with 10% methanol to prepare 100 ppm, 10 ppm
and 1 ppm formaldehyde solutions.

Reagents used for standardization of formaldehyde
stock solutions are: sodium carbonate (certified 99.9%
minimum purity, dried at 120 °C for 2 h, then transferred
to a desiccator, dried to a constant weight and used
as a primary standard); concentrated (98%) sulfuric acid;
0.1 N sulfuric acid (standardized against sodium carbonate
solution); and 12.5% (w/v) sodium sulfite.

Standardization of formaldehyde stock solutions
involves weighing 50 ± 0.5 g of formaldehyde solution
and transferring it to a 250-mL beaker, then adding 25 mL
of 12.5% w/v sodium sulfite (whose pH is adjusted to 9.6
with 0.1 N \( \text{H}_2\text{SO}_4 \)) and titrating to pH 9.6 with 0.1 N
\( \text{H}_2\text{SO}_4 \). The concentration of formaldehyde (in ppm) is
calculated as follows:

\[
\text{Formaldehyde (ppm)} = \frac{(A - B)(C)(D)}{E}
\]

where \( A \) = sulfuric acid solution required to titrate the
sample (mL), \( B \) = sulfuric acid solution required to
titrate the blank (mL), \( C \) = normality of the sulfuric
acid solution (mequiv mL
1), \( D \) = (30 mg mequiv
1 of
\( \text{HCHO} \)) \( \times \) 1000 µg mg
1 or 30 \( \times \) 10³ µg mequiv
1 of
formaldehyde, and \( E \) = amount of sample used (g).
with deionized water and air-dried prior to use. The polarographic analyzer and the automated cell sequencer are warmed up for at least 30 min. Each standard and sample are purged for 5 min with pre-purified nitrogen. A calibration curve is made by analyzing standards and blanks (supporting electrolyte). The standard is reanalyzed after every five or six samples. The peak current (nA) for each standard and sample is recorded. The differential pulse polarogram of formaldehyde hydrazone at a dropping mercury electrode yields a peak at approximately \(-0.850 \text{ V}\). A least squares regression program is used to plot a calibration curve of peak current (nA) vs concentration (total µg) of standards.

6.2.3.6 Calculations The weight in µg corresponding to each response (nA) is recorded from the standard curve. No volume corrections are needed if the standard curve is based upon µg per 10 mL formaldehyde and the volume of the sample determined is identical to the volume of the standards determined.

Corrections for the blanks must be made for each sample as follows:

\[
\text{µg mL}^{-1}\text{HCHO (blank corrected)} = \frac{\text{µg HCHO}}{\text{sample aliquot (mL)}} - \frac{\text{µg blank}}{\text{ blank aliquot (mL)}}
\]

The concentration of formaldehyde in the air sampled can be expressed in mg m\(^{-3}\), which is numerically equivalent to µg L\(^{-1}\).

\[
\text{mg m}^{-3} = \frac{\text{ (corrected µg mL}^{-1}\text{)(sample volume)}}{\text{ (air volume sampled, liters)}}
\]

Another method of expressing concentration is in ppm (corrected to standard conditions of 25 °C and 101.325 kPa):

\[
\text{ppm} = \text{mg m}^{-3} \times \frac{24.45}{\text{MW}}
\]

where 24.45 = molar volume (L mol\(^{-1}\)) of analyte, at 25 °C and 101.325 kPa, and \(\text{MW}\) = molecular weight (g mol\(^{-1}\)) of analyte.

6.2.4 Chromatographic Methods

6.2.4.1 Direct Gas Chromatographic Method Principle. A direct gas chromatographic procedure is suitable for the quantitative determination of formaldehyde. In GC a mobile phase (a carrier gas) and a stationary phase (column packing) are used to separate individual compounds. The carrier gas is nitrogen or helium. The stationary phase is a liquid that has been coated on an inert granular solid, called the column packing, that is held in borosilicate glass tubing. The column is installed in an oven with the inlet attached to a heated injector block and the outlet attached to a detector. Precise and constant temperature control of the injector block, oven and detector is maintained. Stationary phase material and concentration, column length and diameter, oven temperature, carrier gas flow and detector type are the controlled variables. The sample solution is injected through a tetrafluoroethylene-coated silicone rubber septum onto the column with a microsyringe. The samples are vaporized and moved through the column at different rates, depending on differences in partition coefficients between the mobile and stationary phases. As each component passes through the detector a quantitatively proportional change in electrical signal is measured on a strip-chart recorder. The retention time is indicative of the particular component and the peak height/peak area is proportional to its concentration. The detector system may be selected on the basis of specificity and sensitivity needed.

Apparatus. Numerous instruments varying in sophistication and price are available for GC. The basic components are shown in Figure 6. The different parts of the instrument are as follows:

- Carrier gas supply. Carrier gases, which must be chemically inert, include He, Ar, N\(_2\) and H\(_2\). He is the most widely used. Flow rates are controlled by a pressure regulator. Inlet pressure usually ranges from 69 to 345 kPa which leads to flow rates of 25–50 mL min\(^{-1}\).

- Sample injection system. Column efficiency requires that the sample be of a suitable size and be introduced as a “plug” of vapor. A microsyringe is used to inject liquid samples through a rubber or silicone diaphragm into a heated sample port located at the head of the column. For ordinary analytical columns sample sizes vary from 0.1 to 10 µL. Capillary columns require much smaller samples (~10\(^{-3}\) µL).

- Columns. Two types of columns are employed. One type is fabricated from capillary tubing (0.3–0.5 mm i.d.), the bore of which is coated with a very thin film (1 µm) of the liquid phase, and is 10–100 m long. Packed columns are fabricated from glass or metal tubes (1–8 mm i.d.). They are designed to hold solid packing and range from 2 to 20 m in length.

- Solid support for packed columns. Most common supports are derived from diatomaceous earths such as firebrick and kieselguhr. Firebrick, which is sold under trade names such as Chromosorb P\(^{\text{TM}}\), C22 and Sterchamol, has the better strength and larger specific surface area (~4 m\(^2\) g\(^{-1}\)). Its disadvantage lies in the fact that it is more active and hence cannot
be employed with polar compounds. Kieselguhr is more fragile than firebrick and has a smaller surface area (~1 m² g⁻¹) but is less reactive. It is sold under trade names as Chromosorb W™, Celite™, Embacel™, Celatom™, Fluoropak 80™, Teflon 6™, Columpak T™, etc.

Liquid phase. The different compounds used for analysis are Ethofat 60/25, a polyoxyethylene mono-stearate containing an average of 15 ethylene oxide units (MW 938). Other substances investigated are sorbitol, diethylene glycol, mannitol hexaacetate, sucrose octaacetate, Carbowax 6000, Apiezon N and Lac 296 (polyethylene glycol succinate). All substrates are loaded to 10 wt% on the fluorocarbon supports and to 20 wt% on chromosorb supports.

Detectors.

- Thermal conductivity detection (TCD). TCD is based upon changes in the thermal conductivity of the gas stream, measured using a device called a katharometer. TCD detectors are simple, rugged, inexpensive, nonselective, accurate and nondestructive of the sample.
- FID. When compounds are pyrolyzed at the temperature of a H₂/air flame they produce ionic intermediates that provide a mechanism by which electricity can be carried through the flame. The electrical resistance of a flame is very high (10¹² Ω) and the resulting currents are, therefore, minuscule, so an electrometer must be employed for their measurement.
- Electron capture detection (ECD). With electron capture detectors the effluent from the column is passed over a β-emitter such as Ni-63 or tritium (adsorbed on platinum or titanium foil). An electron from the emitter causes ionization of the carrier gas (N₂) and production of a burst of electrons. In the absence of organic species a constant current between a pair of electrodes results from this ionization process. The current decreases, however, in the presence of organic molecules that tend to capture electrons. The response is nonlinear unless the potential across the detector is pulsed. ECD devices are highly sensitive and possess the advantage of not altering the sample significantly.

Reagents. A test solution is prepared from paraformaldehyde, formalin or formalin plus butanol. A formaldehyde standard solution containing 23.83% formaldehyde is prepared by boiling paraformaldehyde in distilled water. The solution is filtered and its formaldehyde content is determined by the standard peroxide method. This solution is used to determine the sensitivity for formaldehyde.

Formalin solution used for the calibration is prepared by diluting previously analyzed formalin with distilled water. A standard reference solution is prepared containing 15 wt% methanol, 47.4 wt% water and 37.6 wt% butanol for routine use as reference.
FORMALDEHYDE, ENVIRONMENTAL ANALYSIS OF

Figure 7 Gas chromatograms of the test and reference solutions. Conditions: column, 5 meter Ethofat 60/25, 10 wt% on columnpak T, column temperature 115°C, flow 43 mL min⁻¹, bridge current 230 mA, sample size 5 µL. Peaks: (1) methanol, (2) water, (3) formaldehyde, (4) butanol. (Reprinted with permission from Bombaugh and Bull. Copyright 1962 American Chemical Society.)

Analytical Procedure. Chromatograms of the test and of the reference solutions are prepared under the operating conditions described in Figure 7, and the areas of the peaks of interest are determined with a polar planimeter or integrator. The peak areas are corrected using Equation (1):

\[ A_c = A_m \frac{S_0}{S_m} \]  \hspace{1cm} (1)

where \( A_c \) = corrected peak area, \( A_m \) = measured peak area, \( S_0 \) = peak area of reference at time of calibration, and \( S_m \) = peak area of reference at the time of analysis.

The corrected peak areas are used to determine the mass \( G \) of each component in the test solution according to Equation (2):

\[ G = \frac{A_c - b}{m} \]  \hspace{1cm} (2)

where \( b \) = intercept determined at the time of calibration, and \( m \) = slope of calibration line. Equations (1) and (2) can be combined to give Equation (3):

\[ \% \text{ of component present} = \frac{[(A_m(S_0/S_m)) - b]100}{m/g} \]  \hspace{1cm} (3)

where \( g \) = grams injected.

6.2.4.2 Derivatization Approaches Requiring Chromatographic Separation A major concern for formaldehyde analysis is the stability of the sample on the sampling media. Derivatization of the compounds either in the sampling device or immediately after collection has improved the stability of samples for many methods. The most commonly used derivatives are 2,4-DNPH and pentafluorophenyl hydrazine (PEPH).

The principle and analysis procedure for formaldehyde using derivatization are same as in the direct chromatography method. In derivatization methods FID is used as the detection method. The preparation of derivatives is described here.

**Preparation of 2,4-Dinitrophenyl Hydrazine Derivatives.**

2,4-Dinitrophenyl hydrazones of formaldehyde are prepared by shaking 100 µL of formaldehyde with 100 mL of a saturated solution of 2,4-DNPH in aqueous 2 N HCl and allowing the mixture to stand at room temperature overnight. The precipitate formed is isolated, washed with 2 N HCl and water and dried over silica gel in a vacuum desiccator. The derivative formed is pure enough for GC analysis and typical gas chromatograms (Figure 8) were recorded using the conditions listed in Table 3.²²

**Preparation of Pentafluorophenyl Hydrazine Derivatives.**

PEPH derivatives are prepared from 0.5 mL of formaldehyde and 0.5 mL of PEPH (1.5 mg mL⁻¹) and one drop of 0.6 M phosphate buffer (pH 7.0) in 10-mL centrifuge tubes by mixing and allowing to stand for 20 min at room temperature.³⁶ The reaction mixture is then saturated with NaCl and one drop of 18 N H₂SO₄ and extracted with 0.2 mL of ethyl acetate containing 50 µg of p-xylene dichloride as internal standard. The extraction is carried out at room temperature. The excess NaCl and the aqueous layer are removed with the aid of syringe with a long needle and dried by adding a small amount of sodium sulfate. An aliquot in ethyl acetate is then applied onto the GC column. The GC conditions are as follows: 2-m glass column packed with 3% XE-60 on 80–100 mesh Celite™ 545, column temperature 120 °C, detector FID temperature 150 °C, injection temperature 150 °C and chart speed 0.25 cm min⁻¹ (Figure 9).

**6.2.4.3 Gas Chromatography/Mass Spectrometry**

The gas chromatographic analysis of derivatives is tedious, requiring chemical reaction, extraction and concentration steps. An interesting approach is the gas chromatography/mass spectrometry (GC/MS) method for the analysis of formaldehyde in air. This method has the advantage of sensitivity and selectivity.³⁸

**Principle.** GC/MS is based upon mass fragmentation techniques, with an initial trapping of formaldehyde on an adsorption tube filled with the molecular sieve 13X. The collected samples are thermally desorbed onto the analytical column (Porapak T) for separation, and then
FORMALDEHYDE, ENVIRONMENTAL ANALYSIS OF

quantified by mass fragmentography (m/z 29 and 30). Advantages of the technique include parts-per-billion sensitivity and selectivity and quantitative recovery.

**Apparatus.** A GC/MS instrument equipped with a mass fragmentation function is used to perform the analysis. A schematic diagram of the GC/MS instrument is shown in Figure 10. The system contains a two-way valve to switch over the carrier gas and block heater for desorption of the sample from the adsorption tube.

- **Adsorption tube.** A 1 g amount of the molecular sieve 13X is packed into a Pyrex tube (15 cm × 4.5 mm i.d.) to form a bed ca. 10 cm long and the tube is secured at both ends with glass wool plugs. Prior to use, the tubes are conditioned by heating at 330 °C overnight and passing nitrogen gas through at a flow rate of 30 mL min⁻¹. The nitrogen gas is purified carefully by passing it through a molecular sieve trap in dry ice–ethanol (−72 °C) in order to prevent adsorption of trace formaldehyde from the nitrogen gas during the cooling process.

- **Reagents.** A stock of formaldehyde is prepared by mixing 1.3 mL formalin (about 35% w/w formaldehyde) and 1 L distilled water. The accurate concentration of formaldehyde in the solution is determined by titration before use. Standards are made up by adding appropriate amounts of this solution to distilled water.

**Analytical Procedure.** Air (1 L) is drawn through an adsorption tube packed with the molecular sieve 13X by a portable pump (Charles Austen Pumps). The sampling flow rate of 100 mL min⁻¹ is controlled by a needle valve. The sampled tubes are sealed with silicon rubber and GC/MS analysis is performed as soon as possible after sampling.

Chromatographic separations are accomplished on Porapak T (80–100 mesh) packed in a glass column (1.8 m × 2 mm i.d.). Desorption of the sample from the adsorbent is carried out at 240 °C with the high-purity helium carrier gas flowing at a rate of 20 mL min⁻¹ for 2 min. During thermal desorption, the formaldehyde transferred onto the analytical column is temporarily trapped at the top for 2 min at a temperature of 30 °C and the carrier gas flow is then switched to the bypass. The mass fragmentograms of the m/z 29 and 30 ions are obtained by temperature programming at 16–150 °C min⁻¹. The concentration of formaldehyde in the samples is determined from the peak heights of the mass fragmentograms of the m/z 30 ion, using a calibration curve prepared from the standard solutions (Figure 11).

**Measurement of Breakthrough Volume.** Breakthrough volumes of adsorption tubes are measured in the following way. The elution volumes of the tubes are monitored for formaldehyde with the GC/MS system. When helium gas is flowing through the tube at room temperature (25 °C), formaldehyde vapor is injected (ca. 100 µg) onto the top of the tube, and the elution volume is taken as the product of the flow rate (20 mL min⁻¹) and the elution time from the tube (which is obtained by subtracting the retention time of formaldehyde on the GC column from the total elution time).
volume is taken as that volume of air which releases a detectable vapor (0.2 ng) from the adsorbent tube.

**Calibration Curve.** The calibration curve for formaldehyde is linear in the range 0–50.0 ng. The detection limit of the method is 0.3 ppb at a signal-to-noise ratio of >3.

**Recovery.** Recoveries for three runs with a high loading of 10 ng formaldehyde per 5 µL aqueous solution and a low loading of 1 ng formaldehyde per 5 µL solution are 101%, with standard deviations of 2 and 14%, respectively.

### 6.2.4.4 High-performance Liquid Chromatography

**Principle.** The limitations of insufficient volatility or thermal stability faced in GC analysis are not present in liquid column chromatography. A sample is introduced into the system via an injector from which it is forced by a flowing stream of solvent, often called the mobile phase, through a narrow bore transport tube to the column. The column is a large tube (2–8 mm i.d.) containing small particles (5–125 µm) known as the stationary phase. The particles alone, when held within the confines of the tubes, comprise the chromatographic bed, and a sample mixture separates as a result of different components adhering to or diffusing into the packing particles. Thus, as the mobile phase is forced through the chromatographic bed, a sample is separated into various zones of sample components, referred to as bands. The bands continue to migrate through the bed, eventually pass out of the column (elution), and pass through one or more detectors. The recorder tracing from the elution of a single band is called a peak. Peaks are usually identified by their retention time, which is the time required to elute the corresponding band from the column.

**Apparatus.** For isocratic operation, a standard HPLC instrument has the following components (Figure 12): (1) a solvent reservoir for the mobile phase; (2) a solvent pump (or pumps) equipped with a damping unit, if a pulsating action results, to force the mobile phase through the chromatographic system; (3) a precolumn (except for bonded phases) and a guard column, the former to presaturate the mobile phase with the stationary phase and latter to prevent contamination of the separation.

![Figure 12 Schematic diagram of HPLC system](image)
FORMALDEHYDE, ENVIRONMENTAL ANALYSIS OF

Derivatives that absorb strongly in UV light have been prepared for HPLC. The method commonly used to determine traces of formaldehyde is to form the 2,4-dinitrophenyl hydrazone and determine the derivative by HPLC. However, for C<sub>1</sub>–C<sub>5</sub> aldehydes 2,4-dinitrophenyl hydrazones have been synthesized and successfully separated by adsorption chromatography. Selim<sup>55</sup> reported the separation of 2,4-dinitrophenyl hydrazones of aldehydes by using reversed-phase HPLC. Beasley et al.<sup>39</sup> reported a new solid sorbent silica gel coated with 2,4-DNPH for formaldehyde. Analysis of the resulting hydrazone derivative is done by HPLC with a UV detector.

Reagents. Reagents include formaldehyde (37%), dimethylformamide (DMF), hydrochloric acid, acetonitrile and silica gel. Paraformaldehyde permeation tubes can be purchased or α-POM permeation tubes can be prepared from α-POM.

The α-POM tubes or the purchased paraformaldehyde permeation tubes can be used successfully to generate a dynamic formaldehyde standard in air.

The α-POM permeation tubes can be used to generate a dynamic formaldehyde standard in air.

The 2,4-DNPH reagent is prepared by adding 0.25 g of 2,4-DNPH to 100 mL of 6 N HCl.

The 2,4-DNPH coated silica gel is prepared as follows. The mixture of 2,4-DNPH in DMF is unstable and must be used quickly. DMF is used because of its superior solvent properties. Silica gel (12.5 g) is placed in a 100-mL round-bottom flask with by 12.5 mL of 6 N HCl. DMF (40 mL) is added to a 100-mL volumetric flask containing 5.0 g 2,4-DNPH. This mixture is swirled for 10–15 s, quickly diluted to the mark with additional DMF and immediately poured through a glass wool plug into the flask containing the silica gel and HCl. The volumetric flask and glass wool are rinsed with an additional 5 mL of DMF, which is also added to the round-bottom flask. The mixture is allowed to stand for 30 min, with occasional swirling, before isolation by vacuum filtration. The coated silica gel may be rinsed sparingly with DMF (2–3 mL). Excessive washing will result in increased capacity for formaldehyde. It is left on the filter paper with continued suction for 1–2 min and then transferred quickly to a 100-mL round-bottom flask. It is dried under vacuum at 55 °C for 1 h with brief turning every 10 min.

The collection device is a glass tube (10 cm × 4 mm i.d. × 6.2 mm o.d.) containing a 300-mg front section and 75-mg backup section of the coated silica gel. The two sections are separated by small plugs of glass wool. Tubes prepared as described here are found to have a pressure drop of 52 kPa in H<sub>2</sub>O at a flow rate of 115 mL min<sup>−1</sup>. They have a capacity of ~123 µg formaldehyde (5 ppm for a 20-L air sample) before significant breakthrough occurs, regardless of humidity.

Air Sampling. Sampling is done by connecting the sampling tube to the Dupont pumps. Formaldehyde loadings are varied by time of collection with constant permeation and flow rates. Typically, the output of the permeation device is set for 1.0 ppm and is sampled at 100–200 mL min<sup>−1</sup>.

Analysis. The front section of the collection tube, including the front glass wool plug, is transferred to a 1.8-g vial containing 2.0 mL acetonitrile. The backup section and the glass wool plug that separates the two section are treated similarly. The vials are stoppered with polypropylene caps (no Bakelite) and allowed to stand overnight.

For analysis 0.2 mL of the desorbing solution is injected in the loop filter port to provide flushing and loading of the 50 µL injection volume. The system also is flushed with acetonitrile between injections. The mobile phase for the analysis is 65 : 35 (v/v) water : acetonitrile, pumped at 2.0 mL min<sup>−1</sup>. A typical chromatogram is shown in Figure 13. Quantitation of this work is done by peak height/peak area using a calibration curve generated from a series of the standards containing 10–400 µg mL<sup>−1</sup> authentic formaldehyde 2,4-dinitrophenyl hydrazone in acetonitrile (corresponding to 0.1–4.6 ppm formaldehyde in air for a 20-L sample). Beasley et al.<sup>39</sup> validated this method over the range 2.5–95 µg of formaldehyde with 94% recovery and relative standard deviation ±0.04.

Figure 13 HPLC chromatogram for injection of 4.6 µg of formaldehyde-2,4-dinitrophenyl hydrazone (equivalent to 1.08 ppm formaldehyde in air, for a 20-L air sample). (Reprinted with permission from Beasley et al.<sup>39</sup> Copyright 1980 American Chemical Society.)
DNPH derivatization followed by HPLC analysis involves pre-column reactions which may be affected by other components in the sample. In addition the resultant signals, absorptivities and conductivities are sensitive to matrix effects. Igawa et al.\textsuperscript{57} have developed an analytical procedure that couples HPLC with a segmented flow analyzer which involves a post-column reaction. Formaldehyde was separated on a reversed-phase C\textsubscript{18} column derivatized with MBTH and detected at 640 nm.

3-Methyl-2-benzothiazole Hydrazone Derivative.
The aldehydes which were separated on the reversed-phase C\textsubscript{18} column are derivatized with MBTH and detected at 640 nm.

The eluent is an acetonitrile–water mixture prepared from HPLC-grade acetonitrile and purified deionized water.

The reagents used in the reaction detector are MBTH (0.5% w/v), Fe\textsuperscript{3+} solution and Triton X-100. MBTH is prepared by dissolving 3-methyl-2-benzothiazolidone hydrazo hydrochloride monohydrate in water to form a 0.5% (w/v) solution. FeCl\textsubscript{3} is prepared by dissolving FeCl\textsubscript{3} \textsubscript{6H\textsubscript{2}O} in 0.01 M HCl (10% w/v). Triton X-100 is prepared by diluting with water to 0.1% (v/v).

The HPLC apparatus is coupled with a rapid flow analyzer. The HPLC apparatus is equipped with a reversed-phase C\textsubscript{18} analytical column and an adsorbosephere C\textsubscript{18}. A guard column is connected just before the analytical column, and there is a stream tubular reactor.

The sample is injected by a variable volume injector. The separation of aldehyde is performed with isocratic elution using a 40:60% or 1:99% by volume acetonitrile : water mixture. The flow rate and the column temperature are maintained at 0.5 mL min\textsuperscript{-1} and 30 °C, respectively. Post-column reaction occurs at the stream tubular reactor. Absorbance of the colored solution is measured intermittently at 640 nm using the bubble gate of the analyzer. The pathlength is 1 cm. The signal is recorded on a chart and concentration is measured from the peak height or peak area, as determined by the integrator (Figure 14).

Calibration is based on comparison of the sample peak height with those obtained by injecting a mixture containing a known concentration of formaldehyde with a 1% acetonitrile–water eluent.

6.2.4.5 Ion Exchange Chromatography IEC is an analytical method combining formaldehyde collection on an oxidizer impregnated with charcoal with subsequent IC analysis of the formaldehyde as formate ions. It has been developed by Kim et al.\textsuperscript{40}

Principle. The essential principle of this technique is an ion exchange process between the mobile phase and the exchange group covalently bound to the stationary phase. The exchange function in anion chromatography is generally a quaternary ammonium base. During the chromatographic process, the counter-ion of the exchange function is exchanged for the sample ion, and for a short time the latter becomes attached to the fixed charge on the resin. Due to variations in the affinities of the species being chromatographed for the stationary phase, a separation of the various sample components is possible.\textsuperscript{58}

Any substance that has a retention time coinciding with that of formate will interfere. A high concentration of any one ion also interferes with the resolution of others but sample dilution overcomes many interferences.

Apparatus. An ion chromatograph (Figure 15) includes an injection valve, a sample loop, an AG4A guard column, an AS4A separator, a self-regenerating suppressor column, a temperature-compensated small volume conductivity cell (4μL) and a recorder capable of full scale response of 2 s or less. An electronic peak integrator is optional. The ion chromatograph should be capable of delivering 2–5 mL eluent min\textsuperscript{-1} at a pressure of 9.65–13.8 MPa.

Reagents. Deionized or distilled water is free from interferences at the minimum detection limit of each constituent. The eluent solution is 5 mM Na\textsubscript{2}B\textsubscript{4}O\textsubscript{7} \cdot 10 H\textsubscript{2}O (borax). Standard solution (100 mg L\textsuperscript{-1}) contains 1.410 g sodium formate dissolved in 1 L water and stored
in plastic bottles in a refrigerator. The working solution (1 ppm) contains 1 mL of standard solution diluted to 100 mL.

Procedure. The air is passed through a solid sorbent tube (4 mm i.d. \times 7 cm long) containing 150 mg of impregnated charcoal at 50–200 mL min\(^{-1}\) for 3–5 h. The charcoal is removed to a tube containing 15.0 mL of 0.1% H\(_2\)O\(_2\) and shaken for 1 h, then sonicated for 20 min. The solution is filtered through a 0.45-\(\mu\)m membrane filter and the sample is injected into an ion chromatograph. After turning on the ion chromatograph the eluent flow rate is adjusted to 2 mL min\(^{-1}\) and the system is allowed to equilibrate for 15–20 min. A stable baseline indicates equilibrium conditions.

Calibration. The approximate retention time of the standard is determined (Figure 16). Concentrations are calculated based upon peak areas of standard that are prepared daily from 100 ppm stock solution. The stock solutions are prepared weekly from the sodium salt of formic acid, spiked with CHCl\(_3\) and stored at 4°C. Typically standard concentrations are in the range 0.1–1 ppm. The standards are run in triplicate. After every five samples the standard is run to check peak response, and if deviation is more than 2% the system should be recalibrated.

The analytical precision is determined by running the 1 ppm standards nine times, and is found to be 1.64%.\(^{(49)}\)

Sample Analysis. The sample is injected into the ion chromatograph and the peak height/peak area and retention time are recorded.

Calculation.

\[ C = HFD \]

where \( C = \) mg formaldehyde L\(^{-1}\); \( H = \) peak height/area, \( F = \) response factor = concentration of standard/height (area) and \( D = \) dilution factor for those samples requiring dilution.
6.2.5 Infrared Spectroscopy

Infrared (IR) gas analyzers depend for their operation upon the fact that some gases and vapors absorb specific wavelengths of IR radiation. The technique uses a conventional double beam IR spectrometer system with a pair of matched gas cells in the two beams. One cell is filled with a reference gas, which is a non-absorbing gas like nitrogen, while the measuring cell contains the sample. The difference in optical absorption detected between the two cells is a measure of the absorption of the sample at the particular wavelength. The selectivity of this technique is high because of characteristic absorption spectra corresponding to the difference in vibrational energy levels of the bands.

Thomson and Keller and Zeller have compiled and published IR spectra of hazardous gases and vapors. Aliphatic aldehydes show strong absorption near 1730 cm\(^{-1}\) (5.75 µm) (1740–1720 cm\(^{-1}\) region) due to C=O stretching. C–H stretching absorption [2825, 2717 (3.54, 3.68 µm)] is seen in the 2830–2695 cm\(^{-1}\) (3.53–3.71 µm) region. Two moderately intense bands are frequently observed in this region. The appearance of two bands is attributed to Fermi resonance between the fundamental aldehyde C–H stretching and the first overtone of the aldehyde C–H bending vibration that usually appears near 1390 cm\(^{-1}\) (7.20 µm).

6.2.5.1 Nondispersive Infrared Analysis

Long-path IR techniques usually involve long cylindrical glass cells (about 5 cm diameter and 100 cm length) filled with gases and end windows of NaCl (transparent down to 650 cm\(^{-1}\)), KBr (transparent down to 400 cm\(^{-1}\)) or CaF\(_2\) (transparent down to 1250 cm\(^{-1}\)). CaF\(_2\) is the most resistant to attack by water but is also much more easily chipped or cracked.

In a nondispersive infrared (NDIR) spectrometer the IR radiation from the source is not dispersed according to wavelength by a prism or grating as in a standard IR spectrometer. It is made very specific for a given compound or type of compound by using the material under investigation as part of the detector. The detector is efficient in that it “sees” all the wavelengths of interest simultaneously.

It is also selective in that interference by another gas at one particular wavelength will be minimized because it is not present at most other wavelengths.

This is the basis of the Luft nondispersive detector shown in Figure 17. Light is split along two paths: in one is a reference cell filled with clean air, in the other is the sample of contaminated air. The detector consists of two sealed chambers filled with the same (pure) gas which is to be determined in the air sample. As less radiation reaches the area C\(_s\), the pressure increase is less than in C\(_r\), so the flexible metal diaphragm D is bent towards the plate P\(_s\) of the differential capacitor P\(_r\)–D–P\(_s\). The chopper then cuts off radiation from both halves and the pressure differential falls off. The output is a series of pulses, the height of which increases with increasing formaldehyde concentration.

6.2.5.2 Fourier Transform Infrared Spectroscopy

In FTIR instruments, the IR spectra are more accurately and more readily obtained in a matter of seconds using the

---

**Figure 17** Nondispersive Luft type IR gas analyzer. A = amplifier, C\(_s\), C\(_r\) = Luft detector cells for sample and reference beams, Ch = chopper, D = thin metal diaphragm, M = mirrors curved to focus beam from source S on to windows W of suitable IR-transparent material, P\(_r\), P\(_s\) = fixed plates of double capacitor P\(_r\)–D–P\(_s\).

**Figure 18** Schematic diagram of FTIR spectrometer. IRSO = IR source and optics, IIRB = incident IR beam, MM = movable mirror, CP = compensator, BS = beam splitter, FM = fixed mirror, SP = sample, TB = transmitted beam, DT = detector, IFS = interferogram signal, IF = interferogram, IN = intensity, PD = path difference, CT = computer, PT = %transmittance, IRSD = IR special display.
mathematical technique called Fourier transformation. Figure 18 shows the schematic diagram of an FTIR instrument. An interferogram is generated as the mirror moves, and the path difference between the two beams changes. The Fourier transformation of the interferogram is done by a computer to decode it and produce the IR spectrum.

Since all wavelengths of IR spectra are measured simultaneously, the method is several times faster than with dispersive instruments. As slits and gratings are not used, the full IR energy is available to be sent through the sample (high energy throughout) so that even a trace of the sample is adequate. This technique is sensitive down to 20 ppb formaldehyde in air and is ideal for determining vehicle emissions. Measurement of formaldehyde by FTIR has been reported by Scott Research Laboratories, Tuazon et al., Haack et al., and Lawson et al. Figure 19 is a schematic diagram of an FTIR system used to monitor pollutants in ambient air. The eight mirror system shown in Figure 19 was exploited by Tuazon et al. in measurements over a period of five years in the Los Angeles basin. The 22.5-m path multiple reflection cell shown afforded a total pathlength in excess of 1 km.

Figure 19 Schematic diagram of an FTIR system used in ambient air studies.

6.2.5.3 Fourier Transform Infrared Spectroscopy for the Measurement of Formaldehyde in Vehicle Exhaust

Measurement of formaldehyde in vehicles exhausts is described here following the method developed by Haack et al.

Apparatus. The general set-up used for vehicle exhaust analysis is depicted in Figure 20. The constituents are a vehicle chassis dynamometer, dilution tunnel and FTIR apparatus connected as shown. The vehicle tailpipe is connected to a 7.6 m x 30.5 cm i.d. dilution tunnel via an insulated pipe. Pure, dry air is used as the diluent for vehicle exhaust. Dilution ratios from 7:1 to 10:1 are used depending upon the anticipated levels of formaldehyde generated by each test vehicle. The dilution of the exhaust ensures that condensation of water does not occur in the unheated FTIR apparatus.

Fourier Transform Infrared Sampling System. The FTIR sampling system is shown in Figure 21. The sample is drawn from the dilution tunnel through an unheated 45.7 m x 0.95 cm i.d. line made of Teflon™ and hence through the Wilks cell of the FTIR apparatus by means
of a rotary vane pump at a flow rate of 25 L min⁻¹ (10 s lag time). The sample in the cell remained at room temperature, while the pressure was maintained at 93 kPa by using a metering valve between the cell and the rotary vane pump. The sample is filtered at the dilution tunnel through a 142-mm diameter quartz fiber filter in a stainless-steel holder at room temperature. The filter holder is heated to 55 °C for diesel-fueled vehicle experiments. The purpose of the filter is to prevent particulate matter from entering and contaminating the FTIR sample line and cell.

Fourier Transform Infrared Spectrometer. As described previously, FTIR spectrometers differ from conventional grating or prism instruments in that wavelength determination is accomplished by modulating each wavelength at its own unique audio-range frequency via a scanning Michelson interferometer. The digital interferogram is frequency analyzed (Fourier transformed) to produce the IR spectrum. The sample cell used is a custom gold-coated Wilks 20-m variable path cell, used in 14th order with an effective pathlength of 21.75 m. A HgCdTe detector exhibiting negligible nonlinearity is used. An absorbance spectrum is generated by calculating the logarithm of the ratio of the corrected spectrum of the tunnel dilution air to the corrected sample spectrum. The formaldehyde IR signal is measured by integrating the absorbance of selected vibration–rotation lines in the C=H stretching region from 2739 to 2827 cm⁻¹. Figure 22 displays the FTIR formaldehyde spectra of a standard and a methanol-fueled vehicle exhaust sample. The exhaust spectrum is generated from one interferogram. By using this standard the formaldehyde diluted exhaust concentration is determined.

6.2.6 Fluorimetric Method
Most of the in situ techniques described earlier require several minutes to several hours to collect sufficient amounts of the samples, depending on the ambient formaldehyde concentration. These techniques have higher detection limits (ppm or ppb) and therefore cannot be used for in situ measurements where formaldehyde occurs in parts per trillion by volume concentration ranges. Air has been discussed by Lazrus et al., Heikes, Heikes et al., and Dong and Dasgupta. A fluorimetric method based on diffusion of atmospheric formaldehyde vapor to an enzyme-coated piezoelectric crystal detector has been developed for automated fluorimetric determination of formaldehyde in air. The unique advantage of enzyme catalysis for atmospheric measurements is the ability of many enzymes to react selectively with a single species within a complex mixture of compounds. The automated instrument consists of device for continuous rapid transfer of formaldehyde vapor from the sample air to water, a peristaltic Technicon Auto Analyzer pump and a fluorometer fitted with a flow cell to analyze the aqueous formaldehyde.

The dissolved formaldehyde reacts reversibly with H₂O to form the dihydroxymethane adduct which is the dominant form in solution. The CH₂(OH)₂ reduces nicotinamide adenine dinucleotide (NAD⁺) to its fluorescent form (NADH), a reaction which is catalyzed by formaldehyde dehydrogenase (FDH). The suggested overall reaction mechanism is shown in Schemes 13 and 14.

\[
\text{CH}_2\text{(OH)}_2 + \text{FDH} \rightarrow \text{HCOO}^- + \text{H}^+ + \text{H}_2\text{FDH}
\]

**Scheme 13**

\[
\text{H}_2\text{FDH} + \text{NAD}^+ \rightarrow \text{NADH} + \text{FDH} + \text{H}^+
\]

**Scheme 14**

The automated technique is free of interferences from common atmospheric constituents, sensitive and relatively fast. The detection limit is 120 pptv. The calibration curve is linear to approximately 100 ppbv. The coefficient of variation is 2% at 20 ppbv formaldehyde. The rise time of the signal from 10 to 90% is 80 s.

6.2.6.1 Reagents

Stock standard solution (0.01 N) is made by dissolving 0.30 g of paraformaldehyde in water (1 L), which is standardized volumetrically as described previously.

Formaldehyde vapor standards are generated by equilibrating air with aqueous formaldehyde standard. The standard generator apparatus (Figure 23) consists of a tube lined with glass-fiber filter paper. A liquid formaldehyde standard runs down the filter while air

![Figure 23 Vapor phase standard generator. Typical air flow rate is <1 L min⁻¹. (Reprinted with permission from Lazrus et al. Copyright 1988 American Chemical Society.)](image-url)
supplied by a pure air generator runs in a counter current flow. The tube is thermostatted (usually at 18 °C). Dilution of this air to yield the desired concentration of formaldehyde occurs in the test manifold. The coefficient of variation for the difference between calculated and observed formaldehyde in vapor phase standards ranging between 1.8 and 4.4 ppbv is 10.3% (n = 11) resulting principally from errors in gas flow control and dilution. No wall losses are detected when using an inlet of PFA (polyfluoroalkene) tubing, with 0.64 cm i.d. and 3 m length. To set the instrument at zero, formaldehyde is initially removed from incoming air by passing it through a molecular sieve trap which is 25.4 mm i.d. and 152.4 mm long. The molecular sieve is 13X (0.32 cm pellets). The efficiency of the molecular sieve trap appears to decline too quickly for it to be useful as a zeroing device in this application. To irreversibly bind formaldehyde, a trap constructed of PFA Teflon® (4 cm i.d., 6 cm long) was filled with silica gel coated with 2,4-DNPH. This collection efficiency, at 1.0 L min⁻¹, is 97% for 7.0 ppbv formaldehyde. When clean air is sampled (0.1–2.0 ppbv formaldehyde), two additional techniques can be used for stabilizing the instrument to zero. The first is simply to use “zero” air free of formaldehyde. The second is to use the reagent blank as the zero signal. The reagent blank is obtained by allowing the scrubbing solution to bypass the air scrubbing coil. The use of “zero” air and the reagent blank yield identical signals and are believed to be the most reliable means of zeroing the instrument at a very low concentration of formaldehyde.

To prepare the FDH reagent, FDH from Pseudomonas putido in the form of lyophilized powder is dissolved in water (16 enzyme units per 100 mL) (one enzyme unit oxidizes 1.0 μmol of formaldehyde to formic acid per minute at pH 7 and 30 °C). This reagent is buffered at pH 8 with 0.01 M Na₂HPO₄.

To prepare the NAD⁺ reagent, 35 mg of 99+% crystalline β-NAD is dissolved in 100 mL water (approximately 5 x 10⁻⁴ M). The pH is adjusted to 4–5 with HCl for stabilization.

6.2.6.2 Experimental Formaldehyde vapor is stripped from the atmosphere by means of concurrently pulling the air sample and scrubbing water through a 28-turn 3 mm i.d. Technicon Auto Analyzer mixing coil (Figure 24). The scrubbing water is adjusted to pH 2.0 with hydrochloric acid and nominally flows at 0.42 mL min⁻¹ through the coil. Air is sampled at 1.0 L min⁻¹ giving a residence time of about 0.3 s. The scrubbing water, which is impelled by the air as it flows through the vertical coil, forms a thin film on the glass surface, providing a large surface for gas exchange. For maximum accuracy, the delivery rate of the pump tube introducing water into the scrubbing coil is calibrated.

![Figure 24 Pyrex glass stripping coil and separator. Typical flow rates are 1.0 L min⁻¹ for air and 0.42 mL min⁻¹ for scrubbing water. (Reprinted with permission from Lazrus et al. Copyright 1988 American Chemical Society.)](image)

The aqueous formaldehyde is isolated from the scrubbing air in a vertical separator column by gravity. It is then mixed with buffer (0.2 M Na₂HPO₄ adjusted to pH 8 with HCl) and led into a five-turn mixing coil. The FDH and NAD⁺ are then added to the reaction stream, followed by a second five-turn mixing coil. The reaction mixture is pumped through a reaction time delay coil (13.2-min delay) to allow production of NADH to completion (Figure 25). A filter is placed in the enzyme line downstream of the pump to remove particles occasionally seen in this reagent. The polycarbonate filter (8.0 μm pore size and 13 mm diameter) is contained in an in-line polycarbonate filter holder. The bubbles are removed from the flow stream by a Technicon debubbler placed immediately upstream of the fluorometer flow cell.

6.2.7 Tunable Diode Laser Absorption Spectroscopy TDLAS is a technique based on IR absorption spectroscopy. Unlike FTIR this technique relies on measuring the absorbance at specific wavelengths due to absorption of IR radiation by various pollutants. However, rather than using a continuous wavelength light source and scanning the entire IR spectrum, TDLAS employs a laser light source of very narrow linewidth which is tunable over a smaller (300 cm⁻¹) wavelength range.

The very high spectral resolution of the lasers allows the measurement of single rotational vibrational lines in the spectrum of the target molecule which leads to excellent specificity. Moreover, the method is highly
sensitive and allows for a very good time resolution. The method is therefore suitable for sampling from aircraft or for the detailed study of temporal variations of photochemically related species and for validating photochemical models of the troposphere in the remote troposphere, particularly where accurate measurements are needed. TDLAS is more useful for following specific pollutants known to be present than for searching for previously unidentified species. Many workers have discussed different types of tunable IR laser sources used in absorption spectroscopy for monitoring of pollutants. Tuning of the emitted wavelength of the diode can be accomplished through variation of one of three possible parameters: applied magnetic field strength, diode temperature and hydrostatic pressure. Temperature, which can be controlled by changing the current through the diode, is the most commonly used.

Several different modulation techniques can be used to increase the signal-to-noise ratio. For example, the laser beam can be mechanically chopped and detected using phase-sensitive detection with a lock-in amplifier. A more commonly used method for accurately measuring small absorbances is to modulate the frequency output of the laser by modulating the current and thus the temperature of the diode. Absorbances down to $10^{-5}$ M can be measured, corresponding to ppb to sub-ppb concentrations at a pathlength of 40 m (e.g. using white cell optics) for many pollutants of atmospheric interest.

The Doppler limited C–H stretching spectrum in the 2700–3000 cm$^{-1}$ region (3.3–3.5 µm) or functional group (carbonyl group) absorption in the 1740 cm$^{-1}$ (5.6 µm) region is used for monitoring of formaldehyde. A continuous wave (CW) difference frequency spectrometer, which operates by mixing on argon ion laser with a tunable dye laser in a non-linear optical crystal (LiNbO$_3$), is used for monitoring formaldehyde in the 3.5-µm region. Pine constructed this type of laser source, which operates in the 2.2–4.2 µm region and achieved a tunable IR output with microwatt power at a resolution of 0.001 cm$^{-1}$.  

**Figure 25** Schematic diagram of the automated fluorometer. (Reprinted with permission from Lazrus et al. Copyright 1988 American Chemical Society.)
A white cell is used in the TDLAS system to provide the long pathlength required to attain the desired sensitivity. The sample is pumped at reduced pressure (3.33 kPa) through the white cell to reduce the overlap between absorption lines of atmospheric constituents. There is also a provision to fit the observed spectra to the known spectral properties of various gases that absorb in the spectral region of interest. A background spectrum is taken in the ambient sample after removing only the formaldehyde. The difference between the ambient and background spectra is due to formaldehyde alone. When the curve is fitted to a database of known spectra the resulting concentration is tied directly to the physical properties of the gas of interest. A calibration with known concentrations is only needed as a check on whether the sampling system efficiently passes the formaldehyde to the optical cell. Formaldehyde has been estimated using TDLAS by Harris et al.,\textsuperscript{(25)} Mackay et al.,\textsuperscript{(27)} Harder et al.,\textsuperscript{(8)} and NASA.\textsuperscript{(74)}

6.2.7.1 Instrumentation A schematic diagram of the instrument developed by Harris et al.\textsuperscript{(25)} is shown in Figure 26. The instrument incorporates two laser source assemblies to enable simultaneous monitoring of two species in the same air sample, and uses line locking of the linear output frequency to the selected absorption features by microprocessor control of the laser operating temperatures. It also incorporates a data acquisition and instrument control system which permits automated operation. The laser output is frequency modulated at 7.5 kHz and synchronously detected at 15 kHz. A switching mirror, S, is first aligned to direct radiation from laser A into the white cell. The computer generates the laser output as a 2f spectrum.

The entrance window on the white cell is mounted at an angle of about 45° with respect to the laser beam and serves as a beam splitter. About 5% of the laser power is reflected through cells (RC1 and RC2) containing high concentrations of the monitored species to detector D. The signal from this detector is demodulated at 7.5 kHz using a phase sensitive detector whose output is compared with a dc voltage to register a reproducible point near the absorption line center on each scan. At each step
of the scan, the software checks to see if the line center has been reached. This approach allows the system to remain locked to the absorption feature while retaining the advantages of scanning the laser output across the whole absorption feature.

Data are accumulated in this manner for a period of for example 3 min, providing an average value of the $2f$ line profiles for the two species during that time. The raw data are analyzed by the program at the end of each averaging period. The analysis program first digitally smooths the data using a least squares algorithm, which is very effective at removing high frequency noise without distorting the $2f$ lineshape if the smoothing window is correctly chosen. After smoothing of the ambient spectrum, either a smoothed background (zero air) spectrum or a least squares fitted low order polynomial, or both, is subtracted to suppress frequency-dependent background structures and/or residual etalon signals in the spectrum.

6.2.7.2 Linearity, Response Time, Sampling Integrity and Detection Limits To assess the relationship between the $2f$ signal and the mixing ratio, signals are measured as a function of formaldehyde mixing ratio determined by adding the output of the permeation device to various flows of clean air. No deviations from linearity are observed up to 50 ppbv.

The response time of the instrument toward changes in formaldehyde mixing ratios is investigated by setting the laser frequency to line center and recording the $2f$ peak signal amplitude as a function of time when calibration gas is suddenly added or removed from the flow at the air inlet. The results showed that the response time for a 90% change in the formaldehyde mixing ratio is a few seconds, corresponding to the residence time of the sampled air in the white cell. At these concentrations, polymerization of formaldehyde on surfaces does not occur and the monomer does not appear to interact strongly with the Teflon® surfaces of the sampling system.

The sampling integrity of the inlet system is confirmed by the observation that no differences in signal could be detected when calibration gas is introduced at the inlet of the sampling line (5 m of 6.25 mm o.d. Teflon® tubing) or directly into the white cell. Further tests compared the signals when a calibration spike is added to dry nitrogen carrier gas, to zero air or to ambient air streams. No effect on the throughput is detected. The laser is operated on individual lines in the 1740-cm$^{-1}$ region of the formaldehyde absorption spectrum. The calibration method removes the need to assign the chosen line(s) spectroscopically or to measure their integrated line strengths. The methods used for determining the system detection limits and avoiding spectroscopic interferences are discussed by Slemr et al. The minimum detectable mixing ratios are derived from reproducibility of the background spectra and low ppbv level calibration mixtures.

The detection limits achieved for formaldehyde are 0.25 ppbv using a 33.5 m optical pathlength and an averaging time of 3 min. The factors governing detection limits have been found to be a combination of random (high frequency) noise arising from the laser and the detector and slow changes (drifts) in the wavelength-dependent background structure. This structure arises because the laser power output varies when the driving current is modulated and swept across the absorption feature. Detection limits could be reduced to $\sim$0.15 ppbv by co-addition of the 3 min spectra to form 30 min averages.

6.2.7.3 Measurement Accuracy The accuracy of the measurements is estimated to be $\pm 20\%$. Determination of the output of the permeation device produces the largest source of error with the uncertainty in the colorimetric procedure assessed at $\pm 10\%$. Additional uncertainties of $\pm 2\%$ are caused by temperature variations of the permeation device and of $\pm 5\%$ from the measurement of the air flow into which the calibration gas is introduced.

Sample pretreatment, the initial stages of an analytical procedure, becomes the essential stage in environmental analysis. The only method of determination of organic compounds in water which avoids the isolation and preconcentration step uses direct injection of an aqueous sample on to a gas chromatographic column. Direct aqueous injection (DAI) is the simplest method for the determination of organic water pollutants. This method is also very fast and easy to automate. The method avoids the problems associated with using solvents (toxic and expensive) and incomplete recovery of the analytes during their isolation from the aqueous phase, the effect of potential contaminants when using solvent or solid-phase extraction (SPE), and losses of the analytes during the enrichment step.

The idea of DAI on to a chromatographic column is very old and for liquid chromatography and ion chromatography was widely applied from the beginning of these techniques. In the beginning of the application of this technique in gas chromatography (GC), packed columns were used. The real issue for the development of GC and the application of DAI is connected with introducing to practical use a capillary column with a polar or non-polar stationary thin liquid film or thin layer. The next, very important step was to introduce a direct injection on-column, which eliminates a lot of problems connected with injection in the split or splitless mode.

The determination of haloforms in water using DAI on to a capillary column and electron capture detection (ECD) was the most spectacular application of this method. The DAI/GC/ECD method was used for determination of haloorganic compounds in the different aqueous samples (tap, surface, swimming pool, and seawaters, beers, juices, soft drinks, and physiological liquids). This method was also used for the determination of semivolatile and nonvolatile haloorganic and other organic compounds in the different aqueous samples.

1 INTRODUCTION

Water, the substance so vital to humans and their well-being, the source and basis of life on earth, has recently become a serious danger to our health and life and to the life and health of flora and fauna. Furthermore, desertification of large areas of the world is now observed, and water, particularly clean water, is rapidly becoming a highly desirable and increasingly expensive commodity. Intensive industrialization of the world has resulted in an increased input of toxic inorganic and organic compounds to waters, drastically reducing the quality of surface waters which are a source of drinking water for a large part of the world population. Groundwater supply, which is basically nonrenewable, is diminishing and, in addition, anthropogenic groundwater pollution has become a fact of life. A majority of anthropogenic
water pollutants are toxic compounds, dangerous not only to humans but also to animals and plants. Consequently, there is a need for continuous monitoring of the degree of pollution of potable and surface waters by anthropogenic inorganic and organic compounds. Excessive concentrations of pollutants, above maximum contaminant levels, not only warn consumers but also signal the existence of uncontrolled discharge of wastes, improperly operating treatment plant, lack of enforcement of legislation dealing with water management, or other violations of environmental laws. In order to be able to monitor environmental pollutants properly and effectively, analysts should have a variety of methods of isolation and determination of these contaminants, taking into account both physico-chemical properties of individual compounds and groups of compounds in addition to characteristics of matrices in which these compounds occur.

A majority of organic compounds in water are of natural origin. This is a large and diversified group of mostly unidentified compounds such as humic and fulvic acids, tannins, peptides, and amino acids. Their total concentration varies from 0.1 mg L\(^{-1}\) for groundwater, through 1–5 mg L\(^{-1}\) for most surface waters, to 20–25 mg L\(^{-1}\) for some waters with the highest concentrations of organic matter\(^{1,2}\). These compounds are predominantly nontoxic, but can be precursors of toxic compounds in the process of water treatment.

Anthropogenic organic compounds present the main hazard to the life and health of humans and flora and fauna. The number of known organic compounds is now estimated to be about 16 million, 2 million of which are compounds produced by synthesis alone. Every year, approximately 250,000 new compounds are synthesized and about 1000 of these are manufactured on an industrial scale. At presently, ca. 70,000 organic compounds are commercially available, with an annual global production of 100–200 million tons. Approximately one-third of all organic compounds produced end up in the environment, including water. Over 700 chemical compounds, including more than 600 organic compounds, many of which are biologically active, have been detected in drinking water samples.

Volatile organohalogen compounds and pesticides are particularly important pollutants among organic compounds as a result of their common use, persistence in the environment, and toxicity. They are primarily anthropogenic. Volatile organohalogen compounds are used mainly as solvents, cleaning and degreasing agents, blowing agents, polymerization modifiers, and heat-exchange fluids. As wastes, they find their way into lakes and rivers, and then into seas and oceans. Their concentrations in water and air are very variable and depend upon atmospheric conditions due to the washing by rain and evaporation from water during long periods of warm weather. It is estimated that the annual global production of organohalogen solvents alone amounts to several million tons.\(^3\)

One of the most important sources of organohalogen compounds, particularly volatile ones, is water disinfection by chlorination\(^{1,3–10}\). The actual disinfecting agent is hypochlorous acid formed in the course of a disproportionation reaction taking place when chlorine dissolves in water. During chlorination, humic and fulvic compounds (so-called precursors), harmless and naturally occurring in water, are converted into organohalogen compounds which are dangerous to human life and health. The largest group of compounds formed during chlorination is the trihalomethane (THM) group. These are chloroform, the most abundant compound, bromodichloromethane, dibromochloromethane, and tribromomethane\(^{1,3–10}\). Organobromine compounds are formed when the water being chlorinated contains a large amount of bromides or when the chlorine used for disinfection is contaminated with bromine. Hypobromous acid formed in the reaction of bromide ions with hypochlorous acid reacts with an organic matrix about 200 times faster than does hypochlorous acid.\(^{10}\) The amount and kind of organohalogen compounds formed depend upon the water pH, the amount of chlorine used and the content of organic matrix (total organic carbon (TOC)) in chlorinated water.\(^{1,3–10}\)

THMs are not the only organohalogen compounds formed in the course of chlorination. Other volatile organochlorine compounds, such as tetrachloromethane, chloroethylenes, 1,1-dichloroethylenes, 1,1,2-trichloroethylenes, tetrachloroethylenes, 1,1,1-trichloroethane, and 1,2-dichloroethane, are also commonly found in chlorinated water. In addition, chlorination of humic substances and organic water pollutants yields a variety of other derivatives, of which over 100 have already been identified, including chlorinated acetone, chlorinated acetonitrile, chloropirin, chloral, chloroacetic acids, chlorinated ethers, chlorophenols, and chlorinated ketones.\(^{3–10}\) Koch and Krasner\(^{10}\) estimated that among organohalogen compounds formed during the chlorination of water, 77% are THMs, 15% haloacetic acids, 3% halonitrides, 4% trichloroacetaldehyde hydrate and 1% the remaining compounds.

Pesticides are another group of organic compounds hazardous to human health and life.\(^{1,11–13}\) They increase crop yields by reducing the amount of a crop that is lost to pests, and control diseases transmitted by insects. Pesticides are necessarily toxic, as they are used in agriculture, industry, and households to kill weeds (herbicides), insects (insecticides), fungi (fungicides), rodents (rodenticides), molluscs (molluscicides), mites (acaricides), roundworms (nematicides), aphids (aphicides), and eggs (ovicides). They are also used as
fumigants, attractants, and repellents.\textsuperscript{(1,11–13)} The chemical structures of pesticides are very diversified, including organohalogen compounds, organophosphates, carbamates, triazines, and phenol derivatives.

2 CLASSIFICATION OF TECHNIQUES FOR THE ISOLATION AND DETERMINATION OF ORGANIC COMPOUNDS IN WATER

Anthropogenic organic compounds occur in water at relatively low concentration levels, but even at this level are dangerous to the life and health of humans and flora and fauna. This low concentration causes, in the majority of cases, the need for isolation and preconcentration of the analytes from the complex water matrix. Sample pretreatment, the initial stage of an analytical procedure, becomes the essential stage in environmental analysis. According to the participants in a survey,\textsuperscript{(14)} among analytical laboratories the sample pretreatment takes up 61\% of total time of analysis and is a source of 30\% of the errors generated during sample analysis. The above data clearly indicate that sample pretreatment, including isolation and preconcentration of the analytes, is an essential step in trace analysis. The methods of isolation and preconcentration of organic compounds from water are closely associated with the kind of analytes, their volatility, polarity, stability, water solubility, solubility in organic solvents, etc. Many techniques for the isolation and preconcentration of the analytes from water have been developed.\textsuperscript{(4,5,11,15–23)} The most popular are solvent or liquid–liquid extraction (LLE), SPE, solid-phase microextraction (SPME) and techniques utilizing the distribution of solute among the liquid and the gaseous phase (headspace (HS), purging). Less commonly used methods are supercritical fluid extraction (SFE), freezing out, lyophilization, vacuum distillation, steam distillation, and membrane processes (reverse osmosis, ultrafiltration, dialysis).\textsuperscript{(4,5,11,15–23)} For final determination, GC with specific detection methods such as ECD, nitrogen–phosphorus detection (NPD) flame photometric detection (FPD), atomic emission detection (AED) and electrolytic conductivity detection (ELCD) or universal methods, such as flame ionization detection (FID) or mass spectrometry (MS) are used. Liquid chromatographic methods with detection methods such as ultraviolet (UV) detection, diode-array detection (DAD), electrochemical detection or fluorescence detection are also often used. The characteristics of typical detectors used in GC are listed in Table 1. A schematic diagram of utilization of various isolation techniques for the determination of organic compounds in water is shown in Figure 1.\textsuperscript{(17)} In Figure 1 are shown two main ways for the determination of organic compounds in water: individual compound or total parameter determination. Total parameters such as TOC, dissolved organic carbon (DOC) and suspended organic carbon (SOC) are used to characterize the content of organic compounds in water. Other parameters are defined in terms of the method of isolation of an organic fraction from water: VOC or purgeable organic carbon (POC), EOC and AOC. However, total parameters measuring the carbon content in an organic fraction are not particularly suitable as an estimate of anthropogenic water pollutants and their hazard to human health, since a decisive majority of organic compounds in water are biogenic.

Two main methods for the isolation and preconcentration of organic contaminants from water are LLE and SPE but, although simple and not requiring sophisticated apparatus, they have a number of drawbacks. More volatile compounds can be evaporated during these operations (e.g. THMs, other volatile halocarbons, volatile hydrocarbons) with a consequent decrease in recovery and low results being obtained. Some compounds are poorly

ENVIRONMENT: WATER AND WASTE

extracted from the water phase (e.g. ketones, alcohols) or the partition coefficient is strongly dependent on the matrix (unknown). The LLE method requires the use of large volumes of expensive, and possibly toxic, solvents. After SPE (except methods using thermal desorption for volatile compounds), solvents are also used, although not in such large quantities. The solvents are subsequently evaporated and after analysis create a problem of storage of hazardous waste. Working with these solvents may require the use of personal protection devices, such as respirators. The formation of emulsions is yet another problem with LLE. The solvents and sorbents used for extraction should be of very high purity, free from traces of the analytes and other potential interferents. Otherwise, a large background is obtained, precluding the determination.

HS techniques\(^4,11,15\) are limited to volatile compounds and the partition coefficient is also strongly dependent on the matrix (unknown) and affects the accuracy. Additionally, some compounds, belonging to priority pollutants, are not purgeable from the water phase (e.g. acrylonitrile, propionitrile).

The only method for the determination of organic compounds in water which avoids the isolation and preconcentration step uses direct injection of an aqueous sample on to a GC column.

3 DETERMINATION OF ORGANIC COMPOUNDS BY DIRECT AQUEOUS INJECTION

DAI\(^4,16,24\) is the simplest method for avoiding the often very complicated steps of isolation and preconcentration of analytes. For analysts the best idea is to introduce the sample directly to the GC column without any pretreatment. This technique also avoids all problems related to the hot vaporizing injection technique by introduction of the sample directly into the oven-thermostated column inlet. However, the aqueous samples, particularly environmental, have a very complex nature of the matrix and a large content of inorganic salts and organic compounds (humic acids, other contaminants). These compounds can rest on the top of column and cause additional retention or deactivation of the column. Some low-volatility compounds can be eluted from the column during a long period of time. After direct introduction of aqueous samples, during evaporation, a
large volume of water vapor is formed. At 20 °C from 1µL of water, 60 mL of carrier gas saturated with water vapor is produced. A large volume of water can deactivate the stationary phase and the layer and change the chromatographic condition of the column. Another problem is retention of water on the chromatographic column. This is, particularly in a packed column, a tedious and time-consuming process. Water also has a high surface tension (poor wetting properties) and poor properties concerning solvent effects.

Most of the detectors used in chromatographic determinations are not compatible with water. This concerns, especially, flame-based detectors or infrared (IR) or other spectroscopic detectors. The flame in an FID or thermionic NPD instrument can be blown out by water. On the other hand, in the case of an IR detector the measurement cell, often made from KBr, can be diluted in water. Relatively resistant to the presence of water are ECD and ion trap detection (ITD) instruments.

### 3.1 Determination of Organic Compounds by Direct Aqueous Injection into Packed Columns

The idea of DAI on to a chromatographic column is very old and for liquid and ion chromatography has been widely applied since the beginning of these techniques, but here water is used as one of the components of the mobile phase. A reversed-phase PRP-1 column, sodium form of Aminex A-5, and a Waters Pak cation-exchange column with a Dionex normal cation suppressor have been used. The application of this technique for GC is more difficult. In the beginning of the application of this technique in GC, packed columns were used.

One of the most popular column packings in the early days was graphitized carbon black (GCB). This sorbent was used by Di Corcia et al. for determination of aliphatic amines (C$_1$–C$_{16}$) in aqueous solution. The application of GC for the determination of strong organic bases, such as amines, was always a difficult analytical problem, because of strong solid–gas interactions, the loss of sample, ghosting phenomena and badly tailed elution. It was very important to prepare the sorbent for packing of the column in a very special way. They had used modifications of Sterling FT-G (Carbopack A) and Vulcan GCB (Carbopack B) deactivated with suitable amounts of KOH and covered with polyethylene glycol (PEG), e.g. PEG-20M or PEG-1500. The GC apparatus used (Carlo Erba Model GI) equipped with FID allowed one to inject an aqueous sample (1.5 µL) directly into the column packing. Water was eluted after analytes. It was found that the use of Carbopack B (60–80 mesh), modified with 0.3% potassium hydroxide and 4.8% PEG 20M, gave the best results with regard to the following: reducing the instability of the selectivity and the retention times of amines on prolonged use of the column, the intolerance of the packing to injections of water, baseline disturbances, and interferences caused by alcohols and peak tailing. The detection limit for this method was about 1 mg L$^{-1}$.

FID does not produce sufficient information for the identification of analyte compounds among the variety of different compounds that could be present in a water sample. Computerized gas chromatography/mass spectrometry (GC/MS) overcomes this difficulty. In 1974, Harris et al. described a method for the direct analysis of water samples by GC/MS. A 1–10 µL sample of water sample was injected onto a Varian Model 1400 GC interfaced with a Finnigan Model 1015 C quadruple mass spectrometer. The different types of packed column used were as follows:

1. stainless-steel tube packed with Gas Chrom Q (60–80 mesh) coated with 5% Carbowax 20M;
2. coiled glass column (2 mm i.d.) packed with acid-washed Chromosorb W (60–80 mesh) coated with 10% free fatty acid phase (FFAP);
3. coiled glass column (2 mm i.d.) packed with Chromosorb 101 (50–60 mesh).

From the column with Gas Chrom Q (1), water was eluted much later than the analytes and so the ion source potential and multiplier were applied immediately after injection and switched off during elution of water. From the column with Chromosorb 101 (3), water was eluted very quickly, so the source and multiplier were not applied and data acquisition was not begun until the water had eluted.

This method can be applied to amines, ketones, alcohols, and aliphatic hydrocarbons, but only for domestic sewage and waste effluent water samples owing to very high detection limits (1–50 mg L$^{-1}$), depending on a variety of factors.

A much better concentration range (from 0.1 to 50 µg L$^{-1}$) was achieved by Fujii, who introduced much larger samples (up to 100 µL). His method, also based on DAI and GC/MS analysis, was dedicated to halorganic compounds present in tap water. Two columns were used: the precolumn contained Chromosorb W AW DMCS (60–80 mesh) coated with 10% diglycerol and the main column packed with Chromosorb W AW DMCS (60–80 mesh) coated with 5% SE-30. The elution time of the overload water peak with the diglycerol precolumn was very long and all organohalogen compounds were eluted much earlier. This method can be applied to all compounds which elute before water, e.g. phenols, alcohols, ketones, hydrocarbons, and amines. The longer diglycerol precolumn should be selected in order to elute the higher boiling compounds before the water.
The analytes should not be eluted on the tail of the overload water peak. The main column makes it possible to achieve the required separation. The column temperature was maintained at 100°C isothermally. On the outlet of the main column a three-way valve was positioned to prevent water (eluting after analytes) from entering the MS detector (possibility of damage to the filament or electron multiplier). High sensitivity and precision were achieved by operation in the mass fragmentography mode. Identification was supported not only by known retention times but also from the selectivity afforded by SIM. Detection limits depended upon the kind of compounds and varied from 0.1 µg L\(^{-1}\) for trichloromethane, dibromomethane, and dichloroethene to 0.8 µg L\(^{-1}\) for tetrachloromethane. The time of analysis for organohalogen compounds was about 6.5 min, but after analysis the column had to be maintained at 100°C for at least 50 min to remove water and other less volatile compounds before the next analysis.

For the determination of haloorganic compounds, highly specific selective detection methods, such as ECD or ELCD (Hall detector) are more suitable. Nicholson et al.\(^{(28)}\) described a method for the determination of haloforms in drinking water using DAI into a GC column (Varian 2400 GC equipped with ECD) packed with Chromosorb 101 (60–80 mesh). Also very interesting is the comparison of the DAI/GC/ECD method with the gas purging GC/ELCD method. Excellent agreement between the two methods was demonstrated. The gas purging method is very popular for the determination of volatile compounds in water but needs additional equipment.

In the DAI/GC/ECD method, 9 µL of aqueous sample volume was injected into the column operated under isothermal conditions (either 130 or 150°C) and a 20-min analysis time was used. The column oven must be operated isothermally to prevent excessive baseline drift. The temperature depended on the range of compounds analyzed. This technique when automated and working with an autosampler allows analyses of up to 60 samples per day. The detection limit for this method for chloroform, bromodichloromethane, chlorodibromomethane, and carbon tetrachloride was at or below 1 µg L\(^{-1}\). The authors observed that the results obtained by DAI/GC/ECD can be treated as the maximum haloform concentration which can be reached while the water is in the distribution system, because of reactions of the precursors and the other haloforms at high injector temperatures. The difference was attributed to nonpurgeable chlorinated compounds, formed as a result of the chlorination process, that supposedly decomposed in the heated injection port of the gas chromatograph to yield chloroform.

Similar investigations concerning the determination of THMs were also conducted by Pfaender et al.\(^{(29)}\) For analysis by DAI they used a Perkin-Elmer Model 900 gas chromatograph equipped with two stainless-steel columns (column for analysis and column for makeup) packed with 50–80 mesh Porapak Q operating at 150°C and with ECD. The novelty introduced by them in the construction of the apparatus (except the column for makeup) was a four-way valve installed in the manifold between the column outlet and the detector inlet. The valve permitted the effluent from the analytical column to be vented while the water peak was emerging and then redirected to the detector. During venting, the effluent from the makeup column was connected to the detector. It had been observed that injection of 1 µL of water into the electron capture detector caused no appreciable changes in its performance, but injection of larger quantities of water caused a decrease in detector sensitivity. Installation of the valve permitted a larger volume of water to be injected without a decrease in detector sensitivity. This made it possible to inject on to the column 20 µL of the sample and the detection limit reached for chloroform was 0.5 µg L\(^{-1}\).

Another possibility for removing water during the determination of haloforms in water after DAI was described by Simonds and Kerns,\(^{(30)}\) water being selectively removed by diffusion across a permselective membrane prior to the sample entering the chromatographic column. Nafion® (a perfluorosulfonic acid polymeric material made by DuPont) with strong adsorption properties for water, was used as a membrane. A volume of 1–20 µL of water was injected into a separate heated (150–200°C) injection port, vaporized and the water vapor permeated through the walls of Nafion® tubing, positioned ahead of the chromatographic column, to a stream of dry nitrogen gas sweeping the outer surface of tubing. Any traces of organic compounds were directed to the chromatographic column and were chromatographed. Hydrocarbons, most aldehydes, esters, and ethers are not removed by the Nafion® tube, whereas highly polar compounds such as alcohols, amines, and certain ketones are partially or wholly removed with the water. Since water is removed before the sample enters the chromatographic column, any appropriate column can be used. Two separate types of apparatus were used during investigations. The first used during preliminary experiments was a Pye 104 (Pye Instruments) gas chromatograph equipped with aluminum tubing maintained isothermally at 60°C and packed with Carbowax 400/Porasil C, Low K (Waters) and an electron capture detector (\(^{63}\)Ni ECD). The second apparatus used was a Varian 2100 gas chromatograph equipped with a glass column maintained isothermally at 75°C and packed with 3% Carbowax 20M coated on Carbopack B (60–80 mesh) and an electron capture detector (\(^{3}H\)-Sc ECD). The
detection limits for haloorganic compounds varied from 0.05 µg L⁻¹ for carbon tetrachloride, 0.1 µg L⁻¹ for trichloroethylene and 1,1,1-trichloroethane, 0.3 µg L⁻¹ for chloroform, 35.0 µg L⁻¹ for 1,2-dichlorobenzene and 1,3-dichlorobenzene to 100.0 µg L⁻¹ for dichloromethane and 1500 µg L⁻¹ for chlorobenzene.

A comparison of the DAI method with a simple direct HS technique was also investigated. Both methods gave similar results.

Loung et al. (31) used DAI techniques to investigate drinking water in London. Water samples were collected in a glass vial equipped with a Mininert valve set into a screw cap which allowed the introduction of 5 µL of water sample by a syringe directly into the chromatographic column. This analysis was carried out using a Hewlett-Packard 5713 A gas chromatograph equipped with a glass column packed with Chromosorb 101 (100–120 mesh) operated isothermally at 150°C and an electron capture detector. Detection limits for THMs under these conditions were about 1 µg L⁻¹.

Hou and Tang (32) used a special column for the rapid elution of water during determination of halocarbons in drinking water. Volumes of 0.4–1 µL of water sample were introduced directly onto the GC column (Hewlett-Packard 5890) packed with GDX-103 (a Chinese sorbent similar to Porapak) coated with 1% of SE-30. The final determinations were carried out with an electron capture detector (⁶³Ni ECD). The detection limits varied from 0.4 µg L⁻¹ for tetrachloromethane, ~1 µg L⁻¹ for chloroform, bromochloromethane and dibromochloromethane to 2.6 µg L⁻¹ for tribromomethane.

DAI was proposed also in the United States Environmental Protection Agency (USEPA) standard method (Method 8010), (33) but only in very limited applications (e.g. aqueous process wastes). In this method first of all the purge-and-trap (P&T) technique had been used for the determination of 39 volatile haloorganic compounds in water. The detection limit for the P&T method varied from 0.02 µg L⁻¹ for 1,1,2-trichloroethane through 0.05 µg L⁻¹ for chloroform up to 0.52 µg L⁻¹ for chloroethane, whereas for DAI it was very approximately 10³ µg L⁻¹. There are two columns which can be used in this method, a stainless-steel column packed with Carbopack-B (60–80 mesh) coated with 1% SP-1000 or a stainless-steel column packed with chemically bonded n-octane on Porasil-C (100–120 mesh). Detection was achieved with a halogen-specific detector.

DAI has also been applied to the determination of other compounds. Fussell and McCalley (34) described a method for the determination of volatile fatty acids (C₂–C₅) and lactic acid in aqueous samples of silage based on direct injection of samples (1–2 µL) on to a glass GC column (Pye Unicam) which was packed with GCB coated with Carbowax 20M. This packing gave improved results compared with porous polymer column materials (Porapak Q, Porapak QS, Chromosorb 101). The final determination was carried out using FID. This method was more selective, more precise, and less time-consuming than a classical distillation procedure. The method gave an excellent linear calibration response for volatile fatty acids from 0 to 500 mg L⁻¹ and for lactic acids from 250 to 10 000 mg L⁻¹. The detection limit varied from 2 mg L⁻¹ for fatty acids to 60 mg L⁻¹ for lactic acid. To protect the column, the quartz-wool insert positioned on the top of the column should be renewed regularly if the samples contain non-volatile compounds. Also, the first few centimeters of packing can be replaced.

Malaiyandi and Goddard (35) used DAI for the determination of amines in steam and boiling industrial waters. The addition of amines to boiling industrial water prevents the corrosion caused by CO₂. However, amines are strongly irritant to the skin, mucous membranes, and respiratory tract, so it is necessary to control their content. Amines are highly hydrophilic, so it is very difficult to isolate them from the aqueous sample without loss of analytes. Additionally, the partition coefficient for amines during LLE is not favorable, so DAI is the best approach for the determination of amines in water. The method was employed for the determination of morpholine, cyclohexylamine, and diethylaminoethanol. Amine analysis under the usual GC conditions suffers from several drawbacks: adsorption or even decomposition in the column, bad tailing and ghosting. In the described method, from 2 to 5 µL of aqueous sample were injected directly on to the GC column packed with GCB (60–80 mesh) coated with 4.8% PEG 20M and 0.4% potassium hydroxide. Temperature programming of the column and FID for final determination were used. To prolong the life of the column packing, a guard insert was placed before the column. This guard insert containing a wad of silanized and ammonia solution-treated glass wool could be removed and reused after cleaning. It protected the column from the accumulation of alkali metal carbonates and hydrogen-carbonates and nonvolatile organic compounds on the top of the column, which can plug the column. The detection limits for morpholine, cyclohexylamine, and diethylaminoethanol varied from 52 to 55 ng for one injection.

### 3.2 Determination of Organic Compounds by Direct Aqueous Injection into a Capillary Column

#### 3.2.1 Capillary Columns in Gas Chromatography

The real issue for the development of GC and the application of DAI is connected with introducing to practical use a capillary column with a polar or non-polar stationary thin-liquid film or thin layer. Different
groups of researchers have dealt with these problems and their applications. The initial work connected with the application of a capillary column for GC was performed by Desty, Schomburg et al., Novotny et al., and van Rijswick and Tesafik. This method was improved and developed by Grob et al.

Initially there were many problems with the preparation of columns, specifically with their repeatability and reproducibility, thermal stability, and fragility. For a long time capillary columns were not widely used. However, capillary columns have many advantages. Compared with packed columns they have a much higher separation efficiency in terms of effective plate numbers per meter and the total effective plate numbers that can be achieved in long columns. Also, tailing is much lower. It is now possible without any problems to prepare or to buy capillary columns which can provide high separation efficiency, defined polarity, and temperature stability. Low-volatility compounds can be eluted without decomposition at low temperatures with moderate retention times, because only small amounts of stationary liquids are contained in long columns. Capillary columns also have very low pressure drops, so long columns and high carrier gas flow-rates can be used.

In the studies by Novotny et al. and Rijswick and Tesafik, special attention was focused on the role of selective surface monolayers in wettability, the deactivation procedure, and the deposition of stationary phases on the capillary column, which are the most important parameters for column efficiency.

Schomburg et al. made and etched a glass capillary column with dry hydrogen chloride and coated the etched surface with a stationary liquid phase (OV-101, LAC-5R-728, Carbowax 20M). The tailing of polar compounds can be reduced by coating the surfaces with a thin film of deactivating agent. Carbowaxes were found to be the best for this purpose. For the determination of aqueous samples, two procedures were used and double-column chromatography was proposed. The capillary columns must be protected against a large volume of water (highly polar solvent), which can change the separation efficiency by destroying the thin-film properties. Water can be trapped in the first column (precolumn) packed with a strongly polar stationary phase, such as Carbowax, and less polar analytes eluted before the water can be chromatographed on the main capillary column. After analysis, water can be back-flushed from the precolumn. The second procedure is to elute water, without passing through the main capillary column before the analytes, using a nonpolar Porapak precolumn, which traps analytes in the very first part. After elution of water, analytes can be back-flushed from the precolumn and with or without trapping (in the mantling tube made of stainless-steel and cooled or heated with a stream of nitrogen) directed to the main capillary column. There are two separate injection ports for each method. In this way, only small, negligible amounts of water are introduced to the capillary column. The other solution is to use two capillary columns, the first as the trap and the second for the main separation.

### 3.2.2 Injection On-column in Gas Chromatography

The next, very important step was to introduce direct injection on-column. Conventional injection had been carried out via an evaporation step: split or splitless injection, the falling needle, or a precolumn. During evaporation, the sample is diluted in carrier gas, causing band broadening and a degradation of the detection limits. All vaporizing injectors possess various dead volumes from which the last traces of water vapor are eluted with a delay. Analytes can be absorbed in the injector, or the high temperature during evaporation can destroy some compounds, causing problems with quantitative determinations. Another problem is connected with the septum used on the top of the injection port. The septum can absorb analytes or emit some volatile components, causing tailing, artifacts, ghost peaks, and baseline drift. The syringe needle can introduce to the injector some trace of organic contaminants and in cutting the material of the septum it can add contaminants of rubber or plastic. The latter can plug the injector or the top of the column. This effect is especially dangerous for a capillary column. On-column injection eliminates many of these problems.

### 3.2.3 Injection On-capillary Column in Gas Chromatography

As far as we know, the first application of direct injection on a large-bore steel capillary column (0.03–0.06 mm i.d.) was described by Zlatkis and Walker. The volume of sample introduced was up to 0.3 µL and the efficiency deteriorated rapidly for larger samples. In the next paper, written by Desty, the introduction of the sample as a layer a few tenths of a micrometer thick on a few millimeters of wire of small enough diameter to enter the capillary column was proposed. Analytes were dissolved in the stationary phase on the top of the column at low temperature without decomposing it.

Application of on-capillary column injection for aqueous samples was realized by Grob et al. Their work was fundamental for the development of the DAI technique. There were many problems to resolve for on-column injection: temperature, pressure, and flow conditions of the injector, kind of syringes used, design and functioning of the on-column injector, and the type of capillary columns and detectors. A syringe is the simplest and safest way to introduce a sample into a capillary column. The volume of sample introduced is well defined,
all the sample volume is introduced to the column and the syringe is easily cleaned. The outer diameter of the syringe needle should be at least 0.05 mm less than the inner diameter of the column. The needle, introduced into the column over a length of several centimeters, should not plug the column and the flow conditions of carrier gas. Some problems are caused by partial sample vaporization out of the hot syringe needle and the difficulty with stabilization of the pressure of the carrier gas at the column inlet during injection, because we have to work without a septum. The sample starts to evaporate at the injection point after deposition on the column wall (after leaving the outlet of the needle in the capillary column), not in the syringe needle (including its tip), so the injector has to be cooled. The injection point has to be sufficiently far from the oven wall inside the oven to reach the controlled oven temperature, but not so far as to prevent evaporation of the sample in the needle. It depends upon the design of the oven, but a 10-mm average distance from the wall of oven to the end of the needle is advised by Grob and Grob. The temperature of injection should be such as to prevent explosive vaporization with a sudden pressure increase, which can flush back part of the sample into the cool injector. The vapor pressure of the water should be below the carrier gas inlet pressure. On-column injection produces a much lower relative standard deviation for all analytes than the conventional injection procedure and no breakdown products were observed.

3.2.4 Determination of Haloforms in Water Using Direct Aqueous Injection on to Capillary Columns

The determination of haloforms in water using DAI on to a capillary column and ECD was the most spectacular application proposed by Grob et al. An apolar, extremely inert column was applied to elute water before the volatile haloorganic compounds. Water should be eluted even before much more volatile compounds such as methylene chloride, but there is a need for strong retention of the apolar halocarbons without broadening of the water peak. Non-volatile compounds and inorganic salts are left in the inlet of column. Water is eluted for a longer time during the analysis of natural samples containing inorganic salts than for model samples prepared from deionized water (the dry inorganic salts retain traces of water). The inlet of the column can be periodically broken off or the precolumn consisting of an empty, 1–1.5-m long fused, deactivated (usually silylated) but uncoated silica capillary column should be applied. The precolumn, which retains nonvolatile compounds, should after some period be shortened or replaced. A capillary column coated with an extremely thick film (about 5 µm) of methylsilicone phase (SE-30) or a slightly more polar, phenyl-containing phase (SE-54) was applied. This film was more suitable than the thick films commonly used (1–2 µm). This thick film causes even very volatile organic compounds to have a relatively long retention time, but it also causes a decrease in column efficiency. For the analysis of high-boiling organic compounds a thinner film of nonpolar stationary phase is recommended.

The column length depends on the compounds to be analyzed, but longer columns result in a decrease in sensitivity. An increase in retention time for halocarbons can be achieved by increasing the column length or the film thickness. Volumes of 0.5–2.0 µL of the aqueous samples were injected on to a capillary column (Carlo Erba Model 4 160 gas chromatograph) operating isothermally (103–104 °C) and connected to an electron capture detector (Carlo Erba 63Ni ECD) heated to 350 °C. Cooler columns can accumulate some residual water, causing baseline drift and poorer resolution of high-volatility halocarbons. At higher column temperatures, water vapor can damage the column and cause peak splitting. The optimal length of the column was established as 25–30 m. On-column injection produced much sharper halocarbon peaks than splitless injection. During on-column injection, analytes are evaporated from the water inside the column, whereas during splitless injection analytes are diluted with the carrier gas in the injector, forming a broad initial band and causing peak broadening and even distortion. The detection limits obtained varied from 0.025 µg L⁻¹ for tetrachloroethylene, through 0.03 µg L⁻¹ for chloroform, up to 0.6 µg L⁻¹ for trichloroethene. For the analysis of heavier halocarbons (e.g. chlorobenzenes), a capillary column coated with a thicker film (0.8 µm) is recommended.

3.2.5 Commercially Available Methods for the Determination of Haloforms in Water Using Direct Aqueous Injection on to Capillary Columns

Application sheets for the determination of halocarbons in drinking water using DAI on to a capillary column are available for Carlo Erba and Hewlett-Packard gas chromatographs equipped with ECD. These are elaborations on the basic work of Grob et al. In the case of the Carlo Erba application sheet, cold on-column injection with secondary cooling, a fused-silica capillary column (FSCC) (30 m x 0.32 mm i.d.) PS 255 (coated with a 5-µm film) and a gas chromatograph [Carlo Erba 4160 high-resolution gas chromatography (HRGC) system] equipped with an electron capture detector (ECD 40/400) were used. The injection volume of the water sample was 2 µL. The column was operated isothermally at 104 °C. The injection temperature was higher than the boiling point of water, so cold-on-column injection with secondary cooling was necessary to prevent sample back-flushing.
To prevent contamination of the analytical column by nonvolatile organic and inorganic compounds, an easily replaceable, uncoated and deactivated precolumn placed before the analytical column was used as a retention gap. The precolumn was connected with the analytical column by a zero dead volume butt connector. The other recommended chromatographic conditions are: detector ECD, operated at 350 °C in the constant-current mode; makeup gas, nitrogen (50 mL min⁻¹); carrier gas, hydrogen (2 mL min⁻¹) and 0.025 g L⁻¹; used, and, as the makeup gas, Ar–CH₄ at a flow-rate of 8 mL min⁻¹. The use of an autosampler (AS 550) for routine application was also advised. The dynamic filling method (using pressurized inert gas) utilized by the automatic sampler avoids gas bubble formation in the syringe, which is responsible for the loss of volatiles and irreproducible injection. Detection limits for chosen compounds were as follows: 0.6 µg L⁻¹ for methylene chloride, 0.03 µg L⁻¹ for 1,1,1-trichloroethane, 0.02 µg L⁻¹ for chloroform, 0.015 µg L⁻¹ for tetrachloromethane, 0.03 µg L⁻¹ for trichloroethylene, and 0.025 µg L⁻¹ for tetrachloroethylene.

Temmerman et al. described a similar method, but with some changes of the chromatographic conditions. They also used a cold on-column injector with secondary cooling and a Carlo Erba 5300 HRGC gas chromatograph equipped with ECD operating at 350 °C. In this method, 1 µL of water sample was injected on-column and used a 1.5 m × 0.53 mm i.d. uncoated and undeactivated FSCC as a retention gap. This was connected by a press-fit connector to a 30 m × 0.53 mm i.d. FSCC coated with a 5-µm film of methylsilicone (DB-1) operating isothermally at 104 °C. The undeactivated retention gap slightly improved the elution of the water peak. As the carrier gas, helium at a flow-rate of 1–2 mL min⁻¹ was used, and, as the makeup gas, Ar–CH₄ at a flow-rate of 60 mL min⁻¹ was used. In comparison with solvent extraction (with pentane), the DAI method gave better recoveries.

Temmerman et al. elaborated on the basic work of Hewlett-Packard Application Note 228-135 which was applied as USEPA Method 502.1–3. This method used cool on-column injection, an HP 7673A automatic sampler, an HP 5890 Series II gas chromatograph equipped with a retention gap (1.5 m × 0.53 mm i.d. uncoated, undeactivated FSCC), a 30 m × 0.53 mm i.d. capillary column coated with a 2.65-µm film of HP-1 and an electron capture detector heated at 300 °C. The other chromatographic conditions were as follows: injection of 1 µL of water sample at 50 °C; oven temperature program, 50–150 °C at 10 °C min⁻¹; detector make-up gas, Ar–CH₄ at a flow-rate of 60 mL min⁻¹; carrier gas, hydrogen at an inlet pressure of 10 kPa. The detection limit was 1 µg L⁻¹ for chloroform and 0.5 µg L⁻¹ for other THMs. The linearity for THM determination was very good up to a concentration of 500 µg L⁻¹.

Hewlett-Packard later introduced some changes. They noticed that the retention gap should have a polar or medium-polarity surface and so should be deactivated with PEG or with a medium-polarity reagent, not with dimethylsilicones or an apolar silylating reagent. The result was that they recommended as the retention gap a 5 m × 0.53 mm i.d. deactivated capillary column, and as the analytical column a 30 m × 0.53 mm i.d. capillary column covered with a 1-µm film of HP-1.

A similar solution for the determination of THMs by DAI using ECD was elaborated by Carmichael and Holmes for Varian Instrument Business Manufacturing Facilities. A septum-equipped programmable detector (special construction) with an on-column glass insert was used for cold on-column injection (without secondary cooling), an uncoated deactivated fused-silica column (4 m × 0.53 mm i.d.) as the retention gap and a 0.53 to 0.52 mm press-fit connector, an analytical column (30 m × 0.32 mm i.d.) coated with a film of DB-624 cyanopropyl stationary phase (1.8 µm) and a sheath foil electron capture detector (⁶⁰Ni ECD) were used to determine THMs. After injection of 1–5 µL of the sample (the injector was held at 60 °C for 0.04 min and then heated to 150 °C at 75 °C min⁻¹), the column was held for 3 min at 104 °C and then heated to 150 °C at 10 °C min⁻¹. The carrier gas used was helium (0.2 m s⁻¹ or 10 psi head pressure) and the makeup gas used was nitrogen (50 mL min⁻¹ for a Varian 3400 and 25 mL min⁻¹ for a Varian 3500 GC). The DB-624 analytical column gives effective resolution of haloforms and has a low retention of water and hypochloric acid. The retention gap should be replaced after a few analyses or solvent-washed. The detection limit was lowered to 0.043 µg L⁻¹ for chloroform, 0.016 µg L⁻¹ for bromodichloromethane, 0.017 µg L⁻¹ for dibromochloromethane and 0.060 µg L⁻¹ for bromoform when a smaller cell volume in ECD was applied. This method was introduced on to the market with success and is used in many laboratories.

3.2.6 Determination of Other Organic Compounds in Water Using Direct Aqueous Injection on to Capillary Columns

DAI on to a capillary column was successfully introduced for the determination of volatile organohalogen compounds in water. The success was due to the very high sensitivity of the electron capture detector routinely used in this method. With other compounds, which are not so volatile and do not contain halogen, it is more difficult. Ellington and Trusty described such a method for the determination of trimethyl and triethyl phosphates in water. The widespread use of these compounds as plasticizers, pesticides, and flame retardants causes
their release into the environment. These compounds are very soluble in water, so their isolation using LLE or SPE is very difficult. They used a Hewlett-Packard 5890 gas chromatograph equipped with an automated cool on-column aqueous injector, with a retention gap of 1–1.5 m x 0.53 mm i.d. uncoated, deactivated FSCC. The analytical column used was a 15 m x 0.53 mm i.d. DB-5 column coated with a 1.0-µm film or a 13 m x 0.55 mm i.d. DB-Wax column coated with a 1.0-µm film. FID at 250 °C was used. The column temperature was held initially at 90 °C for 1 min, then programmed to 115 °C at 5 °C min⁻¹ and to 160 °C at 70 °C min⁻¹ and held at 160 °C for 2 min. The carrier gas used was helium at a flow-rate of 10–12 mL min⁻¹, and nitrogen acted as the makeup gas at a flow-rate of 25 mL min⁻¹. The flow-rates of hydrogen and air were 32 and 330 mL min⁻¹, respectively. The injection volume was 1 µL. The samples were buffered at pH 3 for phthalate and pH 7 or 11 for phosphate. The main problem encountered is the buildup of the buffer salts which necessitates rinsing of the column or periodic replacement of the retention gap. Good linearity and precision in determination were obtained.

A method for the determination of volatile fatty acids using on-column injection of an aqueous solution was described by McCalley. A Hewlett-Packard 5890 gas chromatograph was used with on-column injection (0.5 µL of analyte water or aqueous solution of oxalic acid, 0.03 mol L⁻¹). The analytical column was either a 10 m x 0.53 mm i.d. fused-silica column containing cross-linked FFAP, film thickness 1.0 µm, or a 15 m x 0.55 mm i.d. DB-Wax column coated with a 1.0-µm film. A single flame ionization detector operating at 200 °C was used. An electronically stored blank chromatogram was used to eliminate the effect of stationary phase bleeding during the temperature program. The carrier gas was helium at a flow-rate of 31 cm s⁻¹.

DAI with GC coupled to Fourier transform infrared (FTIR) spectroscopy was used by Payne and Collette for identification of bis(2-chloroethyl) ether hydrolysis products: 2-(2-chloroethoxy)ethanol (2CEE), diethyleneglycol (DEG), p-dioxane (pDOX), 2-chloroethanol (CE) and ethylene glycol (EG). They also used a Hewlett-Packard 5890 gas chromatograph equipped with a cool on-column injection system, comprising a 30 m DB-Wax (a PEG phase), 1.0-µm Megabore column and FTIR with a Digilab FTS-60 spectrometer. This was equipped with a mercury–cadmium–telluride detector using a light pipe-based interface operated at 220 °C. The FTIR detector was connected in series with a thermal conductivity detection (TCD) instrument. The column temperature was programmed from 80 to 220 °C at 15 °C min⁻¹ and held at 220 °C for 10 min. Helium was used as the carrier gas. Between the column outlet and FTIR interface, a Valco six-port valve was installed. During water elution from the column (before the analytes on this column), the outlet of the column was connected to a TCD instrument and, during elution of analytes, to the FTIR interface. The injection volume was 1 µL.

Gurka et al. applied DAI coupled with GC/FTIR or GC/ion trap spectrometry (ITS) for the determination of a wide range (13) of organic compounds, which were water soluble, low-molecular-weight, and poorly or not purgeable efficiently from water. These included alcohols, ketones, nitriles, and esters. They used for this purpose a Hewlett-Packard Model 5965 A IR detector (containing a narrow-band mercury–cadmium–telluride detector) and a Finnigan Model ITS 40 (equipped with a septum programmable injector (SPI) and scanned from 29 to 300 u). Both detectors were interfaced to a gas chromatograph equipped with an on-column injector. In the case of GC/FTIR analysis, a Hewlett-Packard Model 5890 gas chromatograph equipped with a fused-silica capillary column (FSCC) (27.5 m x 0.32 mm i.d.), coated with a 10-µm Pora Plot Q film, was used. After 5 min at 60 °C, the GC column was heated to 200 °C at 10 °C min⁻¹ and held at 200 °C for 8 min. The light pipe and transfer lines were also heated to 220 °C. As the carrier gas, helium was used at a flow-rate of 33 cm s⁻¹. No makeup gas was used. Helium was dried by passing it through a cartridge drier. The detection limits varied from 5 to 100 mg L⁻¹ so this method is not useful for routine analysis of drinking water, but can be used for industrial process streams and effluents.

In the case of GC/ITS analysis, the Varian Model 3400 gas chromatograph equipped with an FSCC (1.5 m x 0.32 mm i.d.) coated with a 0.5-µm polysiloxane film with 5% phenyl groups (PTE-5) and a 30 cm x 0.05 mm i.d. fused-silica restrictor connected between the analytical column and the SPI to limit the flow of carrier gas to the ITS 40 manifold (it should be less than 1.5 mL min⁻¹) was used. After 1 min at 60 °C, the GC column was heated to 240 °C at 16 °C min⁻¹. As the carrier gas, helium at a flow-rate of 45 cm s⁻¹ was used. The injection volume was 2 µL. The detection limits varied from 4 to 200 µg L⁻¹.

The GC/ITS method was improved by Pyle and Gurka for the determination of 27 volatile organic compounds. They had noticed that injections greater than 0.2 µL provided imprecise results caused by residual water eluted together with the analytes, so 0.2 µL was routinely injected on-column. Using similar equipment to before with a Restec column (30 m x 0.53 mm i.d. XTI-5 Megabore FSCC coated with a 1.5-µm film of bonded 5% phenyl and 95% dimethyl polysiloxane liquid phase), they changed the working conditions of the detector, specifying the rf voltage of the ion trap to exclude water ions from the manifold. Single-ion and triple-ion quantitation methods were tested. Better precision...
and detection limits (about twofold) for the triple-ion method were obtained. The detection limits varied from 1.56 µg L⁻¹ for ethylbenzene, through 2.35 µg L⁻¹ for chlorobenzene, 3.19 µg L⁻¹ for benzene and 4.83 µg L⁻¹ for trichloromethane, up to 20.37 µg L⁻¹ for 2-chloroethyl vinyl ether. The total time of analysis was 12 min. In comparison with the P&T method, DAI/GC/ITS is faster, simpler to apply, and has a large dynamic range (from 20 µg L⁻¹ to 20 mg L⁻¹). DAI also shows possibilities for the determination of higher boiling semivolatile compounds.

3.3 Determination of Organic Compounds by Direct Large-volume Aqueous Injection Capillary Gas Chromatography

The typical injection volume for GC is about 1 µL of sample and such a volume was used in the previously described methods. This volume is too small for DAI (without any preconcentration steps) to reach required detection limits for most of the organic pollutants of water dictated by European Union (EU) regulations. The main solution for direct water analysis is to inject much larger volumes of samples, despite water being a very difficult solvent for GC, as was previously described. Water affects the peak shape and resolution, can deactivate analytical columns and can damage the detector, causing a reduction in detection limits. To avoid these difficulties, water should be released after injection from the GC system via an early water vapor exit, before the chromatographic column and detector. The analytes are trapped on some sorbent or liquid layer inside the chromatographic system. This is the basic idea of on-line enrichment GC analysis after direct large-volume injection of aqueous samples.\(^6\)

Zlatkis et al.\(^6\) described a method for the quantitative determination of the trace organic compounds (2-octanone, 5-nonanone, 2-decanone, 2-undecanone, benzaldehyde, and lindane) in aqueous solutions at parts per billion (micrograms per liter) and parts per trillion (nanograms per liter) levels. Up to 400 µL of water sample was injected directly on to a bonded hydrophobic phase capillary column connected to a postcolumn [50 cm × 0.32 mm i.d. empty fused-silica open-tubular capillary column (FSOT)]. The postcolumn was not connected to the detector. The analytes were adsorbed in the main column while water was released by the open exit of the postcolumn. After water had been removed from the main column and the postcolumn, the main column was connected to the detector and adsorbed analytes were thermally desorbed, trapped in the cold trap, and analyzed by GC using the same column operating in reverse or one in series. Less than 0.1 µL of water was trapped in the cold trap. For the final determination FID or ECD (for lindane) was used.

In the case of GC/FID analysis, the Hewlett-Packard gas chromatograph used (HP 5830A) was equipped with a 50 m × 0.32 mm i.d., 0.5-µm film, bonded-phase methylsilica FSOT column, a 50 cm × 0.32 mm i.d. empty FSOT postcolumn and a cold trap (50 cm × 0.37 mm i.d. empty stainless-steel tubing in liquid nitrogen) and FID was used. Injection was performed at room temperature. After removing water (about 15 s), the main column was connected to the cold trap and heated at 200 °C for 20 min, then the oven was cooled, the outlet of the cold trap was connected to the detector and the column was reversed (the end of the column formerly connected to the injector was connected to the detector). Once the cooling from the cold trap ceased, the analysis started. The column was held isothermal for 2 min and then heated at 2 °C min⁻¹. Helium was used as the carrier gas.

In the case of GC/ECD analysis (for lindane) a Varian 3700 GC gas chromatograph equipped with an 11 m × 0.32 mm i.d., 1-µL film DB-5 (equivalent to SE-54) FSOT column as the adsorbing column, a postcolumn and a cold trap as before and a 50 m × 0.32 mm i.d., 0.52-µm film, cross-linked 5% phenyl–methylsilicone FSOT column as the analytical column. ECD was used. Injection was performed at room temperature. After removing water (about 15 s), the adsorbing column was connected to the cold trap and heated at 200 °C for 20 min, then the cold trap was disconnected from the adsorbing column and connected to the analytical column. Once cooling of the cold trap ceased, the analysis started. The temperature of the analytical column was programmed from 50 °C (initial temperature) to 240 °C at 5 °C min⁻¹. Helium was used as the carrier gas and argon with 5% methane (30 mL min⁻¹) as the makeup gas. Two columns were used to decrease the time for ECD stabilization.

Both methods required considerable manual transfer operations and were therefore laborious and time-consuming, but represented the first feasible method based on direct injection of large amounts of aqueous samples on to a capillary column. These ideas were used by other workers to realize on-line enrichment of analytes during direct analysis of large water samples.

Gerhardt and Cortes\(^6\) improved the method for the determination of pesticides using large-volume DAI capillary GC for the determination of chlorpyrifos in well water. A Hewlett-Packard 5890 gas chromatograph was used, equipped with a 10-port valve, and a 20 m × 0.25 mm i.d. nondeactivated FSCC as the inlet (retention gap) connected via a low-dead-volume union with the analytical column (30 m × 0.25 mm i.d., 5% phenyl–methylsilicone capillary with a 0.25-µm film thickness). ECD was used. A 20-µL volume of water sample was injected via the
10-port injection valve equipped with a stainless-steel external sample loop on to the uncoated inlet. The inlet allowed complete solvent vaporization prior to reaching the analytical column. All water passed the analytical column and detector, but collecting and processing of the detector signals started after passing all water vapor. The column was heated for 15 min at 130 °C then increased to 280 °C at 20 °C min⁻¹. Helium was used as the carrier gas (6.4 mL min⁻¹ at 130 °C) and argon–methane (10:90) at a flow-rate 32 mL min⁻¹ as the makeup gas. The detection limit for chlorpyrifos was 0.22 µg L⁻¹ with a linearity range from 0.9 to 18 µg L⁻¹ and with high accuracy and precision. They noted that relatively large volumes of water injected into the capillary column do not affect the peak shape and resolution, even after 150 injections (3 mL of water).

Much higher volumes of water can be introduced using splitless injection with vapor overflow, as proposed by Grob et al. for the determination of triazines (atrazine, prometryn, simazine, terbutylazine, desisopropylatrazine, and desethylatrazine). Water vapor was removed by a vapor outlet beyond the analytical column. A Carlo Erba gas chromatograph (Model 4160) was equipped with an injector containing an insert with a vaporizing chamber (80 mm × 5 mm i.d.) packed with Tenax™ TA (20–35 mesh), a 2 m × 0.32 mm i.d. precolumn coated with a 0.6-µm film of an apolar stationary phase (PEG–Superox 0.6), a 40 cm × 0.32 mm i.d. raw fused-silica column as the vapor outlet, and a 15 m × 0.32 mm i.d. FSCC coated with a 0.4-µm film of Superox and 5% Irganox 1010, and alkali flame ionization detection (AFID)/NPD was used. Up to 400 µL of water sample was injected using a syringe to the injector insert heated at 310 °C. Water vapor and volatile compounds were removed from the system by the precolumn and the open vapor outlet while the compound of interest remained in the precolumn. The temperature of the column during injection was 130 °C. After 2 min the vapor outlet was closed and the released precolumn gas was directed to the analytical column and detector. The temperature program of the column (from 130 to 240 °C at 8 °C min⁻¹) was started 5 min after injection. Hydrogen was used as the carrier gas. The detection limit for triazines was about 0.5 µg L⁻¹, so it was higher than required for routine analysis, where EU standards dictate 0.1 µg L⁻¹ as the maximum acceptable concentration in drinking water.

The idea of direct injection of large amounts of water sample in an adsorbent-packed programmed temperature vaporization (PTV) injector was developed by Engewald et al. Water was removed through the split vent while analytes were trapped on an adsorbent inside the PTV injector. Adsorbents used for such a purpose should have a large breakthrough volume for the analytes and a very low one for water, and they should also be a mechanically and thermally stable and should easily release analytes after heating. They tested Tenax™ TA, Tenax™ GR, Chemipack C18 and GCB from the point of view of breakthrough volumes for pesticides and nitroaromatic compounds. Tenax™ TA was chosen as the best sorbent with regard to the breakthrough volumes for the chosen analytes. They used a Hewlett-Packard HP 5890 Series II gas chromatograph equipped with a PTV injector (cold injection system), a glass insert packed with a 2-cm layer of Tenax™ TA (4.2 mg), a 2 m × 0.32 mm i.d. retention gap, a 25 m × 0.32 mm i.d. column with a 0.2-µm film of CP Sil 19 CB as the analytical column and ECD or NPD. ECD was used for determination of organochlorine and NPD for nitrogen- or phosphorus-containing pesticides and nitrotoluenes. Up to 500 µL of aqueous sample were injected into the injection insert at 50 °C with a split flow of 600 mL min⁻¹. Water was removed from the insert over a 40-min period as the analytes remained on it. Elimination of water can be controlled by means of a thermal conductivity cell placed after the split vent. Desorption was realized at 280 °C for 5 min (splitless) and the analytic compounds were focused by ‘cold trapping’ at a column temperature of 40 °C. The column was then heated to 270 °C at 10 °C min⁻¹. The detection limits varied from 0.01 µg L⁻¹ (dieldrin with ECD) to 0.5 µg L⁻¹ (aldmorph with NPD). Even with extremely water-sensitive NPD, no sensitivity loss was observed after numerous analyses.

This method was applied to the determination of target and non-target pollutants in water from the Elbe River using for the final determination an MS detector in the SIM mode (for target analysis) or SCAN mode (for non-target analysis). A volume of 1 mL or more of aqueous sample was slowly injected (CIS 3 injector) into the insert with sorbent. It is very important in this technique to control the rate of sample injection. Water should be completely evaporated in front of the adsorbent bed in the insert to ensure quantitative enrichment of the analytes from the gas phase. Very important also were parameters such as temperature and structure of the insert and the kind and flow-rate of the carrier gas. A simple back-flush device was developed and installed between the injector and the analytical column to avoid possible damage to the column or detector by water vapor. The detection limit of approximately 0.01 µg L⁻¹ was comparable to that with conventional isolation and preconcentration techniques such as SPE or LLE connected with selective detection (ECD or NPD).

A small change to the chromatographic conditions was used by the same authors for the determination of 12 triazines and their decomposition products in water from the Elbe River. A 500-µL volume of water sample was injected using the CSI 3 cooled injection system directly...
into the Tenax™-packed insert of a PTV injector heated at 50 °C with an injection speed of 10 µL·min⁻¹ and a split flow of 600 mL·min⁻¹ (including 15 mL·min⁻¹ back-flushing). Sample introduction lasted 50 min and then the split vent was closed and the analytes thermally desorbed in the splitless mode to the analytical column. For the chromatographic determination a Hewlett-Packard 5890 Series II gas chromatograph equipped with an SPB-5 column (30 m × 0.25 mm i.d. with a 0.1-µm film thickness) and helium as the carrier gas with an inlet pressure of 1.7 bar was used, with NPD. The injector was heated at an initial temperature of 70 °C for 3.5 min, then heated to 150 °C at 15 °C·min⁻¹, to 175 °C at 3 °C·min⁻¹, to 280 °C at 20 °C·min⁻¹ and held for 2 min at 280 °C. After analysis of samples containing large amounts of nonvolatile organic and inorganic compounds, the insert must be changed frequently. This method can also be used for the determination of polychlorinated biphenyls and polycyclic aromatic hydrocarbons at parts per trillion (nanograms per liter) levels.

### 4 APPLICATION OF DIRECT AQUEOUS INJECTION FOR DETERMINATION OF HALOORGANIC WATER POLLUTANTS IN THE GDAŃSK DISTRICT

DAI on to capillary chromatographic columns connected with a selective electron capture detector was used for the determination of haloorganic compounds in different aqueous samples (tap, surface, swimming pool, and seawater, beers, juices, soft drinks, and physiological liquids).

#### 4.1 Determination of Volatile Haloorganic Compounds in the Tap, Surface and Swimming Pool Waters from the Gdańsk District

The presence of volatile organohalogen compounds in tap and swimming pool water mainly originates from disinfection of the water, most often accomplished by chlorination. Even when other methods are used, such as ozonation, UV irradiation, or application of hydrogen peroxide, chlorine is necessary for water preservation in the water-mains system. About 70% of Gdańsk water is supplied from underground water intakes but 30% comes from treated water. The latter is surface water intake from Straszyn. This water, taken from the Radunia River, is treated by ozonation and at the outlet to the water-mains system by chlorination (to protect it from secondary bacteriological pollution). The water in swimming pools is also treated by chlorination. Chlorination causes very toxic, mutagenic, and carcinogenic volatile haloorganic compounds at relatively high levels (up to 100 µg·L⁻¹ and more) to be present in tap and swimming pool water. The World Health Organization (WHO), the EU and most individual countries, including Poland, have introduced a maximum admissible concentration (MAC) for some organohalogen compounds present in the tap water. There are first of all THMs (trichloromethane, bromodichloromethane, dibromochloromethane, tribromomethane), but also tetrachloromethane, 1,2,2-trichloroethene, 1,1-dichloroethene, 1,1,2,2-tetrachloroethene, 1,2-dichloroethane and 1,1,1-trichloroethane. The MAC varied from 0.3 µg·L⁻¹ for 1,1-dichloroethene (WHO, Norway) to 100 µg·L⁻¹ (EU, WHO, USEPA, UK) for total trihalomethanes (TTHMs) and 350 µg·L⁻¹ for TTHMs (Canada). Typical concentrations of trichloromethane (chloroform), the compound most frequently present in the water treated by chlorination, varied from 1 to 30 µg·L⁻¹; 30 µg·L⁻¹ is the MAC in the directives of the WHO, Poland and UK for chloroform in tap water. DAI on to a capillary GC column with ECD is a suitable method for the determination of organohalogen compounds in this range of concentrations. This method requires a special injector allowing cold on-column injection and special capillary columns. A nonvaporizing, septumless, cold on-column injector with secondary cooling (Grob type) fulfilled nearly all requirements for the good introduction of the sample on to the chromatographic column.

The construction of such an injector, produced by Carlo Erba, is shown in Figure 2. The aqueous sample (1–2 µL) was introduced directly in to the oven-thermostatted capillary GC column inlet using a syringe with an outer diameter of the needle smaller then the inner diameter of the column. Secondary air cooling of the inlet of the column prevented sample evaporation in the syringe needle (including its tip). The evaporation started after deposition of the sample on to the column wall. The sample was mechanically transferred instead of being evaporated, so high-boiling components did not remain in the syringe needle. The secondary cooling was switched on only before and during the sample injection. The primary cooling of the injector body worked permanently. The secondary cooling permitted rapid cooling of the bottom part of the injector attached to the oven, preventing discrimination of compounds at the syringe tip. It also allowed the introduction of a larger volume of sample, which permitted a decrease in the detection limits. The sample was injected at an injector temperature lower, than the solvent boiling point, but at an oven temperature higher than the solvent boiling point.

Nonvolatile inorganic and organic compounds can gradually accumulate at the column inlet which will...
The electron capture detector was operated at 350 °C, which minimizes the residence time of water in the detector, thus improving the sensitivity of the detector. For the identification of the analytes and for quantitative analysis of other organic compounds, GC/MS was used. For the determination of volatile organohalogen compounds (trichloromethane, bromodichloromethane, dibromochloromethane, tribromomethane, tetrachloromethane, trichloroethene, tetrachloroethene, dichloromethane, 1,1,1-trichloroethylene, 1,1,2,2-tetrachloroethylene), DAI into a capillary column and ECD were used. A Carlo Erba Vega 6180 gas chromatograph was applied with ECD (ECD 40/400). The chromatographic conditions were as follows: a 30 m × 0.32 mm i.d. FSCC, coated with bonded 5-µm apolar DB-1 phase (J&W Scientific) or slightly more polar PS-255 (with 1% vinyl groups); a 2 m × 0.32 mm i.d. fused-silica precolumn; temperature program, 103 °C isothermal; injection system, cold on-column with secondary cooling (20 s before injection); detection; ECD at 350 °C with pure nitrogen (99.999%) as the makeup gas (30 mL min⁻¹); carrier gas, hydrogen at 0.4 m s⁻¹; and injection volume, 2 µL. The retention times, standard deviation (P = 95%; n = 7, concentration about 20 µg L⁻¹), and detection limits of volatile organohalogen compounds for the applied columns DB-1 and PS-255 are listed in Table 2. The detection limits were calculated as three times the baseline random noise level.

The DAI/ECD technique has been successfully used for the determination of volatile organohalogen compounds containing one or two carbon atoms (the products of chlorination of humic substances; THMs) in tap water, swimming pool water, and surface water. Typical results of analysis are listed in Tables 3, 4 and 5. An example of a chromatogram of volatile organohalogen compounds obtained using this method is presented in

*a n.d., not detected. Dichloromethane, 1,1,1-trichloroethane, 1,2-dichloroethane and 1,1-dichloroethene were not detected at any of the sampling sites.

Figure 3 Typical chromatogram of volatile organohalogen compounds (DAI/GC/ECD, isothermal). Peaks: 1 = dichloromethane; 2 = trichloromethane; 3 = 1,2-dichloroethane; 4 = tetrachloromethane; 5 = 1,1,1-trichloroethane; 6 = bromodichloromethane; 7 = trichloroethene; 8 = 1,1,2,2-tetrachloroethane; 9 = dibromochloromethane; 10 = tetrachloroethene; 11 = tribromomethane.

Figure 4 Changes in chloroform concentration in the tap water from different sampling sites in the Gdańsk area during the period 1993–97.

1993, in some cases (Gdańsk Suchanino), did the content of chloroform exceed the Polish and WHO standards. At the same time the concentrations of THMs in all districts supplied by surface water intake from Straszyn were relatively high. After changing the water treatment in this water intake from chlorination to ozonation and introducing water filtration with a carbon filter, these concentrations decreased significantly.
The investigations on tap and surface waters were carried out using a DB-1 chromatographic column, on which, unfortunately, bromodichloromethane and trichloroethene were determined as the sum. Bromodichloromethane is a typical product of humic acid chlorination, whereas trichloroethene originates from industrial sewage. It was confirmed by GC/MS that in the tap water in the Gdańsk Zabianka district trichloroethene was present at relatively high concentration (but not exceeding any standards). A similar high concentration of trichloroethene were found in the underground water intake in Sopot, from which this district of Gdańsk was supplied. Unfortunately, some underground water intakes are polluted by industrial sewage, in this case probably from laundries. Trichloroethene was found also in the Kacza River, flowing across the densely populated district of Gdynia, and in the seawater at Gdynia Orłowo, near the mouth of the Kacza River.

The highest concentration of volatile haloorganic compounds was found in the water from the swimming pool (swimming pool of the Technical University of Gdańsk in Gdańsk Wrzeszcz). This water is intensely chlorinated for sanitary purposes. Here a wide range of haloorganic compounds was found: not only THMs, but also dichloromethane, tetrachloromethane, 1,1,1-trichloroethane, and 1,1,2,2-tetracloroethane, etc. The occurrence of bromoorganics compounds was due to the fact that the raw water contained small amounts of bromides. During chlorination, free bromine is formed, which reacts with organic compounds to form organobromine compounds.

The DAI/GC/ECD technique proved to be a good and very useful method for the determination of volatile haloorganic compounds in tap and swimming pool water owing to its simplicity (no isolation and preconcentration steps are necessary), repeatability, reduction of the possibility of sample contamination by the solvent or sorbent used, reduction of possible losses of volatile compounds during additional steps, and low detection limits (0.002–0.1 µg L⁻¹, only for dichloromethane 1 µg L⁻¹) depending on the percentage of halogen in the compound. The detection limit of the method is related to the amount of the analyte in the sample injected on to the column and the volatility of the analytes. On the basis of presented investigations, Biziuk and Czerwiński elaborated a proposal for a Polish Standard Method (PrPN-C-04549-1) for the determination of dichloromethane, trichloromethane, tetrachloromethane, bromodichloromethane, dibromochloromethane, tribromomethane, trichloroethene, tetracloroethene, 1,1,1-trichloroethane, and 1,1,2,2-tetracloroethane in water by GC using direct injection of the sample.

4.2 Application of Direct Aqueous Injection for Determination of Semivolatile and Nonvolatile Haloorganic Water Pollutants

DAI on to capillary chromatographic columns connected with selective ECD has also been used for the determination of semivolatile and nonvolatile haloorganic compounds in different aqueous samples.

In the case of the simultaneous determination of volatile and semivolatile compounds, a longer analytical column with an appropriate oven temperature program and a thinner film layer in the analytical column have to be used. Wolska et al. used for the determination of 12 volatile and semivolatile organohalogen compounds (from 1,2-dichloroethene to dichlorobenzences, trichlorobenzences and hexachlorobutadiene) cold on-column injection (2 µL), a precolumn (2 m x 0.32 mm i.d.) and an Rtx-624 (60 m x 0.32 mm i.d.) column coated with a 1.8-µm film of stationary phase (6% cyanopropyl–94% dimethylpolysiloxane). The oven temperature program was as follows: 104°C for 4 min, then heated to 110°C at 3°C min⁻¹ and to 200°C at 5°C min⁻¹ and held for 1 min at 200°C. The detection limit varied from 0.02 µg L⁻¹ for tetrachloromethane and trichloroethene, through 0.04 µg L⁻¹ for chloromethane to 1.2 µg L⁻¹ for 1,2-dichlorobenzene. The analysis was carried out on water from the Vistula River and Reda River.

In the method routinely used in the laboratory of SAUR–Neptun Gdańsk (water supply and sewage system for Gdańsk) for the determination of volatile and semivolatile haloorganic compounds in tap water, an Rtx-Volatiles column (60 m x 0.32 mm i.d.) coated with a 3-µm film and an oven temperature program (104°C for 1 min, then heated to 160°C at 2.5°C min⁻¹) were used. A typical chromatogram of 15 compounds obtained in this laboratory is shown in Figure 5.

[Figure 5: Typical chromatogram of 15 compounds obtained in the laboratory of SAUR–Neptun Gdańsk.]

It was also possible to use the DAI/GC/ECD method for the determination of pesticides but at high concentrations. This method was performed for the determination of the pesticide destruction ratio during their chemical oxidation in the aqueous phase (our work). Cold on-column injection (2 µL) and an Rtx-5 capillary column (30 m x 0.25 mm i.d.) coated with a 0.25-µm film (5% diphenyl–95% dimethylpolysiloxane) were used. The oven temperature program was as follows: from 60 to 100°C at 30°C min⁻¹ and to 280°C at 10°C min⁻¹, then held for 10 min at 280°C. For lindane, p,p′-DDT and methoxychlor the detection limit was about 0.1 µg L⁻¹.

4.3 The Combination of Thin-layer Headspace Technique and Direct Aqueous Injection for Determination of Haloorganic Water Pollutants

The application of the DAI/GC/ECD method to samples with very complex matrices containing numerous...
inorganic salts or nonvolatile organic compounds and also for low concentrations of analytes creates many problems. Only small amounts of the samples (2 µL) are introduced into the column, which causes a high detection limit. The detection limit of the DAI/GC/ECD method for volatile haloorganic compounds is sufficient for tap and swimming pool water treated by chlorination and for polluted surface waters, but insufficient for unpolluted underground or surface waters. Direct injection of aqueous samples into a GC column cannot be performed for complex matrices such as seawater, wastewater, surface water rich in humic acids, body fluids, mineral waters, soft drinks, beers, and juices. Inorganic salts and nonvolatile organic compounds deposited in the precolumn retain water, causing broadening of the water peak and an increase in the retention time for the analytes. These contaminants can be slowly transferred to the main column and to the detector, affecting the peak shape, deactivating the column, and changing the chromatographic conditions of the column and detector. These drawbacks can be eliminated by application of a combination of the thin-layer HS technique with the DAI method. This combination allows the preconcentration of analytes in the aqueous phase and the matrix to be changed from a complex mixture of inorganic and organic compounds to a solution of analytes in pure water. The thin-layer countercurrent headspace (TLHS) method introduced by Kozłowski et al. is based on passing volatile compounds from the thin layer of aqueous sample to a countercurrently flowing stream of purified air.

The main part of the apparatus for TLHS is a vertically positioned, spirally wound, thermostated glass tube (2 m × 7 mm i.d.) shown in Figure 6. The sample was introduced on the top of the tube and flowed down in the form of a thin film, from which analytes together with water vapor were transferred to the gaseous phase and transported to the final determination. This approach can be used as a different method for the determination of volatile organic compounds, for the determination of total parameters and individual compounds, and also for preparing the sample for DAI analysis. In such a case two TLHS columns have to be used. In the first column, thermostated at a high temperature (up to 90 °C), the analyte compounds were transferred, together with water vapor to a stream of air, and in the second column, cooled at 10–11 °C, water vapor was condensed together with the analytes. The condensate leaving the second column was taken for DAI/GC/ECD analysis. There are very important advantages of such a procedure: the compounds of interest are isolated from the complex aqueous matrix and pre-concentrated in pure water, and it allows determination of volatile organohalogen compounds in beverages (mineral waters, juices, soft drinks) and biological fluids (urine).
5 CONCLUSIONS

DAI is the simplest method for the determination of organic water pollutants that avoids isolation and preconcentration steps.\(^4,16,17,74\) This method is also very fast and easy to automate. The DAI/GC/ECD method is very useful for the determination of volatile and semivolatile organohalogen compounds in tap, swimming pool and surface waters and also for the determination of pesticides and other compounds which are present in water at sufficient concentrations for detection. The method avoids the problems associated with using solvents (toxic and expensive) and incomplete recovery of the analytes during their isolation from the aqueous phase, the effect of potential contaminants when using solvent or SPE, and losses of the analytes during the enrichment step.

The application of the DAI/GC/ECD method to samples with very complex matrices containing numerous inorganic salts or nonvolatile organic compounds, and for low concentrations of analytes, creates many problems. These drawbacks can be eliminated by the application of a combination of the thin-layer HS technique and the DAI method. This combination allows the preconcentration of analytes in the aqueous phase and changes the matrix from a complex mixture of inorganic and organic compounds to a solution of analytes in pure water.

The best method for the determination of pesticides and other nonvolatile compounds is the direct injection of large amounts of water samples in an adsorbent-packed PTV injector with removal of water vapor from the GC system via an early water vapor exit, before the chromatographic column and detector.

When capillary gas chromatography (GC) is coupled with atomic emission detection (AED), mixtures of volatile and semivolatile organic compounds are first separated based on different retention in a capillary GC column, whereafter the separated compounds are introduced directly into a helium (or argon) plasma. The high temperature of this plasma results in atomization of each of the separated compounds followed by excitation of the constituent atoms. From the excited states, the atoms emit light of characteristic wavelengths which are monitored continuously during the chromatographic separation by an optical spectrometer. This results in element-selective chromatograms, where all elements from the periodic table (except helium or argon) may be detected by a simple change of wavelength. Since atomic lines are narrow and often intense, GC/AED provides high elemental selectivity and acceptable sensitivity. Theoretically, every element from the periodic table (except helium or argon) may be detected by a simple change of wavelength. Since all emission lines are present in the plasma simultaneously, either single- or multichannel detection is possible. Compared with the array of selective detectors responding to one or two elements (e.g. flame photometric detection (FPD), nitrogen–phosphorus detection (NPD), sulfur chemiluminescence detection (SCD), oxygen–flame ionization detection (O-FID)), this multielemental capability represents a major improvement in terms of versatility.

The attractive features of GC/AED were reported for the first time in 1965 by McCormick et al. with an atmospheric pressure argon microwave induced plasma (MIP) coupled to packed column GC. Although the period 1965–1975 also saw research into direct current discharges, most GC/AED research was carried out...
with systems utilizing argon MIPs or reduced-pressure helium MIPs. Unfortunately, the excitation potential of the argon plasmas was insufficient for the detection of several nonmetallic elements, and the evacuation equipment required to produce low-pressure helium plasmas was complex. Therefore, the introduction of the TM010 cavity by Beenakker in 1976 represented a distinct technical improvement in the field of GC/AED because this permitted helium MIPs to be sustained at atmospheric pressure.\(^1\)

Implementation of the TM\(0_{10}\) cavity by other workers was reported from 1978–1980, which almost terminated the interest for reduced-pressure MIP systems. Although most effort has been focused on MIP systems, after 1980, successful GC detection was accomplished with several alternative discharges, including a 25 kHz helium after-glow device,\(^2\) a 350 kHz radio frequency helium plasma,\(^3\,4\) a 60 Hz alternating current helium plasma,\(^5\) a 27.18 MHz capacitively coupled helium plasma,\(^6\) and a 27.12 MHz stabilized capacitively coupled helium plasma.\(^7\) In addition, with argon at atmospheric pressure, direct current plasmas (DCPs)\(^8\) and inductively coupled plasmas (ICPs)\(^9\) have been evaluated, but both plasma systems suffered from poor excitation characteristics for several important nonmetallic elements and from a large consumption of high-purity argon.

GC/AED was carried out solely with laboratory-built instrumentation until the late 1970s, when the first commercial atomic emission detector for GC was introduced by Applied Chromatography Systems. This equipment was based on a reduced-pressure helium MIP and a Rowland circle spectrometer with 12 fixed channels for simultaneous multielement detection.\(^10\)

However, the popularity was low, and even a modified version based on an atmospheric-pressure helium MIP sustained in a TM\(0_{10}\) cavity was implemented only in a limited number of research laboratories. In 1989, a second attempt was made by Hewlett-Packard to commercialize an atomic emission detector for GC. A totally automated benchtop system was introduced, which utilized an atmospheric-pressure helium MIP for analyte excitation and a photodiode array for the monitoring of atomic emission.\(^11,12\)

The photodiode array, which covered the wavelength range from 160–800 nm in 25 nm portions, provided simultaneous multielement detection, multipoint spectral background correction, and elemental confirmation by atomic emission spectra. From the same company, an improved version of this atomic emission detector was recently introduced as a less expensive second-generation instrument with enhanced sensitivity. The two commercially available GC/AED systems from Hewlett-Packard have increased the interest for the technique substantially, and several environmental applications of GC/AED have emerged in recent years. Below, advantages and limitations of GC/AED for environmental analysis are discussed and some of the most interesting environmental applications are reviewed. Principal attention is focused on results obtained with the commercial system, while only a few data from home-built systems are included owing to the difficulties of reproducing this type of complex instrumentation.

### 2 Selectivity and Sensitivity Considerations

Environmental samples are typically very complex with a large number of matrix components, among which
the analytes of interest are present at low concentration levels. Therefore, both selectivity and DLs are important parameters for the successful determination of most environmental micropollutants. In this section, attention will be focused on both of these parameters in order to understand the advantages and the limitations of GC/AED for environmental analysis.

As atomic emission lines are very narrow, overlap from different elements is normally not a problem in GC/AED. However, emission spectra from helium plasmas utilized for GC/AED normally also contain molecular bands (originating from incomplete atomization or from atomic recombinations) which are generally relatively broad. Unfortunately, these may interfere with the atomic lines of interest causing false positive signals (interferences) or negative baseline excursions. Therefore, in order to realize the full potential of the narrow atomic emission lines and to ensure high elemental selectivity, spectral background correction is of great importance in GC/AED. With commercial instrumentation, this is accomplished utilizing a photodiode array for the optical measurements, where continuous multipoint data correction results in very high selectivity for the most important elements found in GC amenable compounds. This is illustrated in Table 1, where the selectivity for several metallic and nonmetallic elements has been determined relative to carbon. With chlorine as an example (selectivity value of 27 000), 27 000 ng carbon (from a hydrocarbon) is required to produce the same signal on the chlorine channel as obtained from 1 ng of chlorine. For practical work with environmental samples, the high elemental selectivities obtained by GC/AED is obviously a major advantage. Organic micropollutants containing heteroatoms (such as Cl, Br, S, Sn, and Hg) may be selectively detected even in very complicated extracts where the resolving power of GC is insufficient. This is illustrated in Figure 2, where GC/AED was utilized for the detection of polychlorinated biphenyls (PCBs) in a highly contaminated marine sediment. In spite of the high background from a crude oil matrix, the PCBs emerged as distinct peaks in the highly selective chlorine trace. Thus, the PCBs were easily located in the chlorine trace and quantitative analysis was rapidly performed because no interferences distorted the peak areas. The highly contaminated sediment sample was also exposed to analysis by GC/MS, but this technique suffered from serious interference when operated both in the low- and high-resolution modes (Figure 2). Thus, although selected ion monitoring was utilized, localization and quantitation of the PCBs were almost impossible based on the GC/MS results.

In addition to selectivity considerations, DLs of GC/AED are of great importance in evaluating the potential for environmental analysis. As illustrated in Table 1 for the commercial system, DLs of GC/AED are generally at the low picograms per second level. Unfortunately, values for the different elements vary by a factor of 200 depending on several factors such as atomic line intensity, excitation potential, and natural background in the plasma. For oxygen, an important element in environmental micropollutants, the DL is relatively high and therefore the practical utility of O-selective detection by GC/AED is strongly limited for environmental applications. DLs for chlorine and bromine, which are important elements within environmental monitoring, were relatively high for the first generation of the Hewlett-Packard GC/AED, but significantly lower values have been reported especially for chlorine with the new version. Thus, especially with the second generation of GC/AED, the technique may be an alternative for the determination of pesticides and polyhalogenated compounds such as PCBs (discussed in detail in sections 5.4 and 5.5). For sulfur, phosphorus, and most of the metallic elements, DLs are at the low picograms per second level supporting the idea that compounds containing these elements may be monitored at relatively low concentration levels by GC/AED.

From the discussion above, high elemental selectivity is the major advantage of GC/AED for environmental analysis. Thus, organic micropollutants containing heteroatoms may be selectively detected in complicated samples without serious interference, and time-consuming sample cleanup may be reduced. However, for some elements DLs are relatively high, which may limit the applicability of the technique or which may call for extensive analyte preconcentration in order to match

*a Selectivities were defined as the ratio of the response per nanogram of element to the response per nanogram of carbon.

*b DLs were defined as the amount of element required to produce a peak twice the noise level, divided by the full width at half-height of the peak in seconds.

the low concentration levels typical for environmental samples.

3 COMPOUND INDEPENDENT CALIBRATION FOR QUANTITATIVE ANALYSIS

During detection, the compounds separated by GC are atomized within the AED and emission is measured from excited atoms. Therefore, in theory, the detector response per element (area counts per nanogram of element) should be independent of the molecular structure from which it originated. For quantitative purposes, this should enable universal calibration where a large number of different compounds are quantified based on a single elemental calibration curve (e.g. for chlorine) obtained for a randomly selected reference compound. Unfortunately, for practical work, this type of universal calibration is somewhat complicated by discrimination during GC injection and by chemical reactions/spectral interferences occurring within the plasma. As illustrated in Table 2 for some PCBs, deviations up to 10% occurred when the chlorine signal from a standard solution of PCB no. 128 was utilized for the quantitation of the other PCBs included in Table 2. Nevertheless, for the determination of organic micropollutants, purchase of reference material is expensive and in several cases, reference standards for the compounds are not commercially available. Thus, for applications where very high accuracy is not required, analysis by GC/AED and universal calibration may be a very fast and simple concept to obtain quantitative data.
4 ESTIMATION OF MOLECULAR FORMULAS

With GC/AED operated in the multielement selective mode, where several different elements are monitored simultaneously, the resulting element-selective chromatograms directly give qualitative information about the constituent elements for each of the separated compounds. With peak no. 5 in Figure 3 as an example, where halogenated alkylbenzenes were detected in nickel industry wastewater, the element-selective chromatograms proved that C, H, and Cl were all present in the compound, while Br was not a constituent of this particular compound. In addition to this, since elemental responses are almost independent of molecular structures (as discussed in section 3), the element-selective chromatograms also contain quantitative information about the elemental composition for each of the separated compounds. Thus, based on simple calibration and multielemental detection, empirical/molecular formulas may be calculated based on GC/AED. This is illustrated in Table 3, where the molecular formula for several halogenated alkylbenzenes present in nickel refinery wastewater (Figure 3) was calculated based on dichlorobenzene as reference.\(^{(18)}\)

Although deviations up to 30% from correct values were observed in some cases, the approximate empirical formulas were utilized to support rapid analyte identification. For target compound analysis, where analyte identification principally is based on retention time data obtained with standard solutions of the components of interest, empirical formulas calculated by GC/AED may significantly improve the reliability of analyte identifications. For nontarget purposes, however, where retention time information normally is not available, identification based solely on GC/AED is unreliable and should be based principally on GC with mass spectrometric or infrared detection.\(^{(19,20)}\) Although identification is based on GC/MS, results from GC/AED may be of great interest to complement mass spectral data. This is illustrated in Figure 4, where chromatograms from both GC/MS and GC/AED analysis of an extract of a pulp mill effluent are shown.\(^{(19)}\) The compound corresponding to peak no. 4 was identified as tetrachlorothiophene (C\(_4\)Cl\(_4\)S) based on
library search on the GC/MS system. This conclusion was supported by the GC/AED results proving that C, Cl, and S were present in the compound while H and O were absent. For peak no. 5, no library mass spectrum was available and manual interpretation was necessary. The mass spectrum (Figure 4) revealed the presence of three chlorine atoms and a molecular mass of 216. Unfortunately, the mass spectrum also contained fragments from co-eluting compounds, and further interpretation was therefore difficult. However, the GC/AED results

<sup>a</sup> Chlorine response factors normalized against congener no. 105.

demonstrated that C, H, S, Cl, and O were all present in the compound. Based on this additional information, and assuming also that peak no. 5 was a thiophene, the compound contained one S atom, three Cl atoms, and at least four C atoms (C<sub>4</sub>Cl<sub>3</sub>S corresponds to 185 mass units). The remaining mass difference up to 216 was 31, and for this part of the molecule, the GC/AED results proved the presence of a single O atom. The 31 mass units probably corresponded to a methoxy group (–OCH<sub>3</sub>), and the compound was suspected to be an isomer of trichloromethoxythiophene.

5 ENVIRONMENTAL APPLICATIONS

Based on the discussion in sections 2, 3, and 4, the major limitation of GC/AED is related to relatively high DLs for some of the nonmetallic elements, while the major advantages are related to the high selectivity, the multielemental capability, and the possibilities of performing universal calibration (quantitative analysis) as well as estimating empirical/molecular formulas. Based on these characteristics, important environmental applications will be reviewed in this section (section 5).

5.1 Tin-containing Compounds

Substantial research has been reported on the GC/AED determination of organotin compounds originally used as antifouling paints on ships, slimicides, pesticides, and as stabilizers in polyvinyl chloride. Thus, organotin compounds have been determined in sediments,<sup>21–27</sup> soil,<sup>23</sup> water,<sup>22,26–31</sup> and biological samples<sup>21,24,25</sup> by GC/AED. An example is illustrated in Figure 5, where tin-organic compounds were detected in mussel tissue.<sup>24</sup> Excellent selectivity has been reported for GC/AED operated in the Sn-selective mode. For complex environmental samples, the selectivity of GC/AED significantly exceeded both GC/MS<sup>20</sup> and GC/FPD.<sup>21</sup> In addition to the high selectivity, the presence of

The DL of the commercial GC/AED has been reported to be comparable with GC/FPD,\(^\text{27}\) which is the most popular detector for Sn-selective detection. GC with atomic absorption spectrometry has also been utilized for Sn-selective detection, but this technique was 1–2 orders of magnitude less sensitive than GC/AED.\(^\text{24,27}\)

When operated in the selected ion monitoring mode, GC/MS was found to provide only slightly better DLs than GC/AED\(^\text{26}\) supporting the idea that GC/AED is highly attractive for Sn-selective detection. With GC/AED, organotin compounds have been detected down to the 0.1-ng L\(^{-1}\) level in water samples\(^\text{28–31}\) and to the 0.2-ng g\(^{-1}\) level in sediments.\(^\text{23,25}\)

While quantification by GC/MS required references for each of the compounds of interest, several tin-organic compounds were confirmed in the case of GC/AED utilizing atomic emission spectra obtained by the photodiode array and stored during each GC analysis.\(^\text{21}\)

### Figure 4

GC analysis of an extract of a pulp mill effluent by (a) GC/MS and by (b) GC/AED in the C-, H-, Cl-, S-, and O-selective modes.\(^\text{19}\) (Reproduced from Chromatographia, 35, 193–198, 1993, with permission from Vieweg.)
have been quantified by GC/AED utilizing universal calibration. In addition, tin-organic compounds have been identified based on empirical formulas calculated from GC/AED results.

5.2 Lead-containing Compounds
In addition to tin-organic compounds, GC/AED has been successfully applied for the determination of lead-containing compounds in water, road dust, and snow. With emphasis on organolead compounds used as antiknock additives in gasoline, GC/AED was found to be substantially more sensitive than GC coupled with atomic absorption spectrometry, the latter of which has been the most popular technique for Pb-selective detection in capillary GC. Thus, with GC/AED, organolead compounds were detected at the 0.1–2-ng L\(^{-1}\) level in water and down to the femtogram per gram level in snow. As for tin, GC/AED is very attractive also for lead compounds because of excellent selectivity and sensitivity.

5.3 Mercury-containing Compounds
Organomercury compounds have been utilized in paints, wood preservatives, paper, and pesticides, and this class of...
compounds is of great importance within environmental monitoring. GC/AED operated in the Hg-selective mode has been used for the determination of organomercury compounds present in biological samples and in water. Compared with gas chromatography/electron capture detection (GC/ECD), which is in frequent use for the detection of organomercurials, the selectivity was superior utilizing GC/AED while DLs of the two detectors were comparable. Thus, with GC/AED, organomercury compounds were detected down to the low nanogram per liter level in water.

Owing to the simultaneous multielement capability of GC/AED, several reports have emerged where tin, lead, and mercury compounds have been determined simultaneously in biological material, soil, and water. An example of this is illustrated in Figure 6, where both organotin and organolead compounds were found in river water. This, in addition to excellent selectivity and sensitivity, suggests that GC/AED is a very attractive technique for the determination of organometallic compounds in environmental samples.

5.4 Pesticides

Several publications have focused on the GC/AED determination of pesticides in environmental and agricultural samples. This broad class of compounds, which are produced industrially as agricultural chemicals, are particularly good candidates for GC/AED analysis since they are rich in heteroatoms such as chlorine, bromine, fluorine, phosphorus, sulfur, nitrogen, and oxygen. Thus, pesticides have been detected in different vegetables, soil, and water utilizing GC/AED. An example is illustrated in Figure 7, where several pesticides were detected in an onion sample by GC/AED. Excellent selectivity has been reported in the chlorine-selective mode for different pesticides present in agricultural products, while the established ECD (electron capture detection) and electrolytic conductivity detection (ELCD) devices suffered from matrix-related interferences. Thus, a GC/AED screening method has been tentatively approved by the US Environmental Protection Agency for inclusion in the Update IV of the SW-846 methods. In addition, GC/AED was found to provide accurate quantitation based on a single chlorine calibration curve (universal calibration). Unfortunately, the pesticide DL in the chlorine-selective mode of the first generation of the commercial GC/AED system was found to be a factor of 10^2–10^4 higher than for GC/ECD. Thus, extensive analyte preconcentration was required to detect organochlorine pesticides by GC/AED at the 0.01 ppm level in agricultural matrices. With the second generation of the commercial GC/AED system, the sensitivity...
problem is expected to decrease, and GC/AED pesticide DLs (concentration units) have been improved by a factor of 100 compared with 1-ml injections by performing large volume injections (100 ml) with a solvent vapor exit in front of the analytical column.\(^{49,52}\)

In addition to chlorine-selective detection, GC/AED in the bromine-, phosphorus-, sulfur-, and nitrogen-selective modes has been reported for the determination of pesticides. While bromine-selective detection is used only occasionally, several papers have emerged utilizing phosphorus-selective detection. The selectivity has been reported to be excellent in different agricultural matrices, and superior to results with both NPD and FPD detection.\(^{42,43}\) The phosphorus DL of GC/AED was found to be comparable with FPD,\(^{43}\) but significantly higher than for NPD.\(^{54}\) Nevertheless, organophosphorus pesticides have been detected down to the 0.01-ppm level in plant foodstuffs by GC/AED utilizing 1 ml injections.\(^{42,43}\) With 100 ml injections, even lower DLs have been obtained in the phosphorus-selective mode utilizing a solvent vapor exit in front of the analytical column.\(^{51,52}\) Quantitative results from GC/AED were in excellent accord with data from NPD, and GC/AED was also found to enable accurate quantitation based on universal calibration in the phosphorus-selective mode.\(^{48}\)

Some of the commercial pesticides also contain sulfur, and these may be selectively detected by GC/AED operated in the sulfur-selective mode. With the commercial GC/AED system, which is relatively sensitive towards sulfur (Table 1), DLs for sulfur-containing pesticides were lower than with FPD,\(^ {43}\) and the linearity problems of the FPD were eliminated.\(^ {55}\) Some pesticides also contain nitrogen and oxygen, but GC/AED is relatively insensitive towards these elements owing to atmospheric contamination of the plasma. Nevertheless, pesticides have been detected by GC/AED in several environmental samples utilizing nitrogen-selective detection. The method was limited to pesticides present above the 1.5–25-ng level in the final extracts, and the GC/AED DLs were found to be a factor of $10^3$–$10^4$ higher than for NPD.\(^ {54}\)

### 5.5 Chlorinated Biphenyls and Phenols

Among the large number of polyhalogenated organic micropollutants included in environmental monitoring...
5.6 Other Compounds Containing Nonmetallic Elements

Above, attention was focused on organic micropollutants containing metallic elements (Sn, Pb, Hg), pesticides, PCBs, and CPs. For all of these contaminants, substantial research has been documented within the literature utilizing the commercial GC/AED system, and GC/AED has been demonstrated to be an attractive alternative to existing methods. In addition to the above mentioned components, several other organic micropollutants have been detected by GC/AED, including polychlorinated dibenzodioxins (PCDDs), volatile organochlorines, trichloroacetic acid, chlorinated by-products of humic and fulvic acids, chlorinated aromatics, polybrominated diphenyls (PBBs), polybrominated diphenylethers (PBDEs), iodated herbicides, volatile sulfur compounds, nitrosubstituted aromatics, and nitro musks. More information on these applications as well as others can be found in a review article concerned with environmental applications of GC/AED.\(^{61}\)

6 CURRENT STATUS AND FUTURE DIRECTIONS

The literature reviewed in the present paper has demonstrated the great potential of GC/AED for analysis of organic micropollutants. Owing to the elemental capability, GC/AED enables rapid screening by elemental content of environmental samples, provides important structural information complementary to mass spectral data, and enables simplified quantitation based on universal calibration with a single elemental calibration curve. Particularly for environmental analysis, which frequently is complicated by matrix constituents, the very high elemental selectivity of GC/AED may reduce both interference and the demands of sample cleanup. However, as pointed out above, DLs of GC/AED are relatively high for some elements and extensive analyte preconcentration may be crucial. This, in combination with the lack of low-price commercially available instrumentation, currently limits the propagation of GC/AED in environmental laboratories.

For the future, therefore, it is hoped that the number of companies committed to producing GC/AED instrumentation will increase to reduce the price level of this highly versatile technology. With some further effort to improve DLs and to include the concept in standard procedures for the monitoring of organic micropollutants, GC/AED may rapidly become a “work horse” in laboratories concerned with environmental chemistry.

1 INTRODUCTION

1.1 Hazardous Amines from Environmental Sources

As environmental issues and global environmental change are generating an increasing amount of attention worldwide, the occurrence and toxicity of hazardous chemicals in the biosphere have received a great deal of attention in recent years. As technology progressed and man’s appetite for a carefree life expanded, the problems of environmental pollution became more complex and difficult to alleviate. The three main categories of pollution are water pollution, air pollution and soil pollution, and knowledge of these types of pollution has become an urgent requirement for the protection of the terrestrial environment. The environment contains a variety of naturally occurring and anthropogenic pollutants to which humans are exposed. Moreover, every year many new substances are synthesized that differ radically from the natural products that exist in biosystems. Many of these compounds are not biodegradable and will thus progressively pollute the environment. Among the many environmental pollutants, the occurrence and determination of amines have recently received a great deal of attention. These amines occur in a number of ambient environments such as air, water, soil and foods, and have become a source of serious social and hygienic problems.

Aliphatic and aromatic mono-, di- and polyamines are naturally occurring compounds formed as metabolic products in microorganisms, plants and animals, in which the principal routes of amine formation include the decarboxylation of amino acids, amination of carbonyl compounds and degradation of nitrogen-containing compounds. These amines are considered to play a significant role as storage sources of nitrogen and precursors for the synthesis of hormones, alkaloids, nucleic acids and proteins. Amines are also widely used as raw materials or at an intermediate stage in the manufacture of industrial chemicals. In particular, aromatic amines such as aniline and its substituted analogs, phenylenediamine and diphenylamine, have been widely used as industrial intermediates in the manufacture of carbamate and urethane pesticides, dyestuffs, cosmetics and medicines. These amines have also been employed in the rubber industry as antioxidants and antiozonants and as components in epoxy and polyurethane polymers. An additional source for amines in the environment is the abiotic and biotic degradation of animal waste, domestic waste and industrial products. Many of these amines have been discharged into the atmosphere and water from anthropogenic sources such as cattle feedlots and near livestock buildings.
incineration, sewage treatment, automobile exhaust, cigarette smoke, soil, and various industries. These amines have also been detected in biological samples. Many amines have an unpleasant smell and are hazardous to health, i.e. as sensitizers and irritants to the skin, eye, mucous membrane and respiratory tract. Some amines are also suspected to be allergenic and mutagenic or carcinogenic substances owing to their adsorption tendency in tissues. In particular, the toxicity of aromatic amines to mammals and fish is well established, and many of these amines are known to be highly mutagenic and carcinogenic in and to form adducts with proteins and DNA. Several polycyclic aromatic amines such as benzidine, 4-aminobiphenyl and 2-naphthylamine have been also classified by the International Agency for Research on Cancer (IARC) as known human carcinogens.

Aliphatic and aromatic amines not only are toxic in themselves but also become toxic N-nitrosamines through chemical reactions with nitrosating agents such as nitrite or nitrate. In general, the nitrosation of amines occurs in the human diet, the environment and in vivo in the stomach or small intestine of experimental animals. The reaction of nitrosating agents with primary amines produces short-lived alkylating species that react with other compounds in the matrix to generate products (mainly alcohols) devoid of toxic activity in the relevant concentrations. The nitrosation of secondary amines leads to the formation of stable N-nitrosamines whereas that of tertiary amines produces a range of labile N-nitroso products. Although the reaction pathways are uncertain, it has also been demonstrated in model experiments that amines react with NO and OH radicals in air to form nitrosamines and nitramines.

Moreover, it is considered that volatile N-nitrosamines in cigarette smoke are formed from the decarboxylation of N-nitrosamino acids, pyrolytic nitrosation of secondary amines and concentrated decarboxylation/nitrosation of amino acids during combustion processes. N-Nitrosamines are widely distributed in foodstuffs and various human environments such as indoor and outdoor air, combustion smoke, water, sediment, household dishwashing liquids, foods, rubber products, metalworking fluids, drug formulations and agricultural chemical formulations. Furthermore, some N-nitrosamines have been detected in human gastric juice, saliva and cervical mucus. N-Nitrosamines represent a major class of important chemical mutagens, carcinogens, teratogens and immunotoxic agents, which have been described as a serious hazard to human health. Recent developments in environmental carcinogenesis have demonstrated that N-nitrosamines lead to a wide variety of tumors in many animals, which are likely to result in the formation of DNA adducts. The toxicity of N-nitrosamines can be manifested even at the micrograms per kilogram level.

A new series of heterocyclic amines formed during heating of amino acids, proteins, creatinine and sugars are potent mutagens in the Ames/Salmonella assay. Many of these mutagenic heterocyclic amines have been isolated and identified not only from various proteinaceous foods including cooked meats and fish, but also from environmental components such as airborne particles and diesel-exhaust particles. Combustion smoke, indoor air, cooking fumes, rainwater and river water. Moreover, some mutagenic heterocyclic amines have been detected in biological samples such as urine, plasma, bile and feces. These facts suggest that heterocyclic amines may be emitted into the atmosphere through combustion of various materials such as foods, wood, grass, garbage and petroleum, and discharged into the water through domestic waste and human waste, although their mechanisms have not been determined. These amines have much higher mutagenic activity than typical mutagens/carcinogens such as aflatoxin B1, AF-2 and benzo[a]pyrene and have been verified to be carcinogenic in rats and mice. These compounds induced tumors in the liver, small and large intestine, Zymbal gland, clitoral gland, skin, oral cavity and mammary gland in rats, and the liver, forestomach, lung, hematopoietic system, lymphoid tissue and blood vessels in mice. 2-Amino-3-methylimidazo[4,5-f]quinoline (IQ) was also found to be carcinogenic in the monkey, inducing hepatocellular carcinomas. Moreover, recent investigations revealed that heterocyclic amines also possess cardiototoxic effects and various pharmacotoxicological activities such as convulsant activity and potent inhibitory effects on platelet function and dopamine metabolism. However, significant risks to human health and the environment through long-term exposure and bioaccumulation of heterocyclic amines are scientifically unclear.

1.2 Objective and Scope

The presence, identity and quantity of amines in the environment should be established to evaluate possible health hazards. In many cases, environmental amines are present at very low concentration and are often found among a myriad of other compounds from which they must be separated and identified. Therefore, analytical methodology for the isolation and quantification of these amines needs selective and sensitive detection. The present article is concerned with the utilization of the
selective gas chromatography (GC) detectors for amine analysis and their application for the determination of amines in environmental samples. The article consists of two parts. In the first part (section 2), general aspects of the selective detection of amines by GC are surveyed according to the detector types. In the second part (section 3), the applications of selective GC methods in environmental analysis are considered according to the amine types. The article covers not only aliphatic and aromatic primary, secondary and tertiary amines but also N-nitrosamines and heterocyclic amines that often occur in various environments as highly toxic compounds. References that have appeared in the past two decades are cited. General aspects of GC detectors have been reviewed in several books. General aspects of environmental analysis by GC have also been detailed in several books and reviews.

2 SELECTIVE DETECTORS FOR ANALYSIS OF AMINES BY GAS CHROMATOGRAPHY

2.1 Amine Analysis by Gas Chromatography

GC has been widely used for amine analysis because of its inherent advantages of simplicity, high resolving power, high sensitivity, short analysis time and low cost. However, GC analysis of free amines generally has some inherent problems related to the difficulty in handling low-molecular-mass amines because of their high water solubility and high volatility. Therefore, these amines are difficult to extract from water and are not easily chromatographed owing to their polarity. Furthermore, amines tend to be adsorbed and decomposed on the columns, and readily give tailed elution peaks, ghosting phenomena and low detector sensitivity. The adsorption tendency in the analytical systems, i.e. in sample vessels, injection system, glass wool and GC column, decreases in the order primary > secondary > tertiary amines, and it is generally more difficult to chromatograph aliphatic than aromatic amines. A common method of overcoming these problems is to convert such polar compounds into relatively nonpolar derivatives more suitable for GC analysis. Derivatization methods have been employed to reduce the polarity of the amino group and improve GC properties. Derivatization reactions, often selective for amine type (primary, secondary, tertiary), have also been used to improve the detection and separation of these amines. A number of derivatives such as acyl, silyl, dinitrophenyl, permethyl, Schiff base, carbamate, sulfonamide and phosphonamide compounds have been used for this purpose. For example, introducing halogen- and phosphorus-containing groups in the molecule enhances the response of the electron-capture detector (ECD) and flame photometric detector (FPD), respectively. These derivatization reactions were described in detail in previous review. For amine analysis, a wide variety of detectors such as the thermionic detector, FPD, ECD, electrolytic conductivity detector (ELCD) and chemiluminescent detector (CLD) can be used, and offer increased selectivity for specific amines. Furthermore, the combined technique of gas chromatography/mass spectrometry (GC/MS) can provide structure information for the unequivocal identification of amines and these amines can be determined with mass-selective detector (MSD) based on a selected-ion monitoring (SIM). By using these detectors, subnanogram detection limits can be achieved. GC detectors for environmental amine analysis are summarized in Table 1. Although most detectors respond directly to amines, some detectors, such as the FPD and ECD, need conversion of amines into suitable derivatives prior to detection.

2.2 Thermionic Detector

The thermionic detector, which evolved from the flame ionization detector (FID), is particularly suitable for the analysis of compounds containing nitrogen and phosphorus. There are two types of thermionic detectors depending on whether a flame is present in or absent in the detector system. In general, a flame-type thermionic detector is called a flame thermionic detector (FTD) or alkali flame ionization detector (AFID), and a flameless-type detector is called a thermionic specific detector (TSD) or nitrogen–phosphorus detector (NPD). The flame type can also detect halogen-containing compounds, but the flameless type selectively respond only to N- and P-containing compounds. A diagram of a Hewlett-Packard NPD is shown in Figure 1.

Although the mechanism of the response of the thermionic detector for N- and P-containing compounds is not fully understood, a widely accepted explanation is as follows. The normal FID ion collection assembly is replaced with a collector that has a small alumina cylinder coated with a rubidium salt (active element), which is heated electrically, creating a thermionic source. In this environment, N- and P-containing organic compounds are ionized. The detector collects the ions and measures the resulting current with an electrometer. The flame in the NPD is not ignited, but rather is adjusted to give a low-temperature plasma. This plasma is not used to heat the collector, but only for ion production and dissociation as the organic compounds eluted from the column. For N-containing compounds, pyrolysis takes place, producing intermediate stable CN radicals and then the radicals formed take electrons from the excited atom of the alkali
metal, resulting in a cyanide ion. A positive alkali metal ion migrates to the collector electrode and again liberates an electron. Therefore, compounds not containing a C–N bond, such as nitrogen gas, nitrogen oxides and ammonia, cannot respond to the NPD.

Thermionic detectors require hydrogen and air as with the FID, but at lower flow rates. Therefore, normal FID-type ionizations are minimal, and the selectivity ratios for detection of N- and P-containing compounds versus carbon detection are 3.5 × 10^4 : 1 and 7.5 × 10^4 : 1.

Figure 1 Diagram of a NPD designed for optimal performance with capillary columns. (Reproduced by permission of Hewlett-Packard from K.J. Hyer, P. Sandra, \textit{High Resolution Gas Chromatography}, 3rd edition, Hewlett-Packard, Avondale, PA, Chapters 4–19, 1989.)

respectively. The sensitivity of a thermionic detector is about 0.4–10 pg for N-containing compounds and 0.1–1 pg for P-containing compounds, and it is about 50–500 times more sensitive for nitrogen and phosphorus, respectively, than the FID. The main disadvantage of this detector is that its performance deteriorates with time. The alkali metal salt employed as the bead is continuously lost during the operation of the detector. Furthermore, the thermionic detector is not usable with columns of liquid phases containing halogen, phosphorus or nitrogen such as XE-60 and OV-210. In addition, the use of column, supports, glass wool treated with phosphoric acid and leak-detection fluids should be avoided to preserve the lifetime of the active element.
The thermionic detector is one of the most popular selective detectors for the GC analysis of amines and is used for the analyses of various amines such as aliphatic and aromatic amines, N-nitrosamines, and heterocyclic amines. Kijima reported that some aliphatic and aromatic amines can be detected at the femtomole level with a TSD. Kataoka and Kijima developed a simple and rapid derivatization method for the GC analysis of heterocyclic amines. Ten heterocyclic amines were determined as their N-dimethylaminomethylene derivatives with an NPD. Skarping et al. reported that some aliphatic and aromatic amines can be detected at the femtomole level with a TSD.

### 2.3 Flame Photometric Detector

The FPD, based on a chemiluminescent species produced during the burning process in a hydrogen-rich flame, is a selective detector for compounds containing sulfur and phosphorus. The emission of S-containing compounds ranges from 390 to 480 nm and that of P-containing compounds from 480 to 580 nm. By choosing a filter having a transmission window of wavelength 390–410 nm for S-containing compounds or 520–560 nm for P-containing compounds, the maximum emission from S- or P-containing compounds can be sensed by the photomultiplier. The emission of hydrocarbons is between 390 and 520 nm, and therefore the emission from the background hydrocarbons will be almost negligible.

A diagram of a Hewlett-Packard FPD is shown in Figure 4. The detector is essentially an FID equipped with a filter that can be changed according to the desired wavelength for sulfur or phosphorus. The end of the capillary column is led into the flame jet where the column eluate mixes with hydrogen flow and is burned. The light emitted passes through two heat filters and then through the selective filter and finally on to the photomultiplier. The chemical reactions that occur in the flame and emission zone are complex depending on the gas flows and temperature. Sulfur and phosphorus are detected as S=S and HPO molecules, respectively. These molecules are created in a metastable state and, when they decay, they release energy in the form of a photon of a specific wavelength. The light emitted from S-containing compounds is not linear.
with concentration owing to the reactions in the flame, but is approximately proportional to the square of the sulfur atom concentration. The selectivity ratio for detection of S- or P-containing compounds versus carbon detection is 10^4:1. The sensitivity of the FPD is about 20 pg for S-containing compounds and 1 pg for P-containing compounds. One serious problem with the FPD is the quenching or reabsorption of the light emitted by the selected species. Hydrocarbon quenching occurs from collisions when the peak of S-containing compounds is co-eluted with another hydrocarbon in the environment, it can also detect amino compounds is co-eluted with another hydrocarbon in high concentrations due to collisional energy absorption, competing chemical reactions or the reabsorption of the photon by an inactivated species, can also occur at high concentrations of the heteroatom species. Precise control of the gas flow to the detector virtually eliminates quenching of the detector response.

Although the FPD is widely used for S- and P-containing compounds such as agricultural chemicals and SO₂ in the environment, it can also detect amino compounds by conversion into their S- or P-containing derivatives. Hamano et al. reported that primary and secondary aliphatic amines could be detected as their N-dialkylthiophosphoryl derivatives with an FPD in the P mode. In particular, secondary amines can be selectively converted into their N-diethylthiophosphoryl derivatives after treatment with \( \alpha \)-phthaldialdehyde (OPA), because OPA reacts only with primary amino groups. As shown in Figure 6(a–d), primary amines are also derivatized without OPA treatment and detected with an FPD, but they are not detected at all with OPA pretreatment. On the other hand, secondary amines are detected irrespective of OPA pretreatment, because these amines do not react with OPA. This technique is also applied to the determination of N-nitrosamines, which are denitrosated with hydrobromic acid to produce the corresponding secondary amines and then derivatized.

### 2.4 Electron-capture Detector

The ECD, which consists of a radioactive source such as \(^{63}\)Ni, is selective detector for halogenated or nitrated compounds, organometallics and conjugated carbonyls. Electron-capture detection involves the following three steps: generation of thermal energy electrons, capture of some of these electrons by an electrophilic compound and measurement of the unreacted electrons. In order to produce capturable (low-energy) thermal electrons, the carrier gas is ionized by \( \beta \)-particles from a radioactive source placed in the cell. This electron flow produces a small current, which is collected and measured by a suitable amplifier. When the sample molecule is introduced into the cell, electrons are captured by the sample, resulting in a decreased current. The detector can be used in two ways: either with a constant potential applied across the cell (dc mode) or with a pulse potential across the cell (pulse mode). In the dc mode, hydrogen or nitrogen can be used as the carrier gas and a small potential (a few volts) is applied across the cell just sufficient to collect all the electrons available and provide a small standing current. When an electron-capturing molecule enters the cell, the electrons are captured by the molecule and the molecules become charged. The mobility of the captured electrons is much reduced compared with the free electrons and therefore the electrode current falls dramatically. On the other hand, in the pulse mode, a mixture of 10% methane in argon is usually used as the carrier gas and the electron-capturing environment is different. The period of the pulsed potential is adjusted such that relatively few of the slow negatively charged molecules reach the anode, but the faster moving electrons are all collected. A diagram of a Hewlett-Packard ECD is shown in Figure 7. The anode and cavity are in a “pi and cup” geometry, and the radioactive source is \(^{63}\)Ni plated on the cup. Although the selectivity
depends on the affinity of compounds for the electrode, the selectivity ratio for detection of polyhalogenated compounds versus carbon detection is $10^5 - 10^6 : 1$. The ECD is extremely sensitive, probably the most sensitive GC detector available. Although the sensitivity of the ECD depends on the molecular structure, that of chlorinated compounds is about 0.05–1 pg. For successful electron-capture detection, it is important that carrier and purge gases are very clean and dry (99.999%).

Although the ECD is widely used in the detection and analysis of halogenated compounds, in particular pesticides, it can also detect amino compounds by conversion into halogen-containing derivatives.\(^{(32-34,120,194,201-205)}\) Miyamoto et al.\(^{(201)}\) determined selectively some primary amines as their $N$-benzenesulfonyl-$N$-trifluoroacetyl derivatives by gas chromatography/electron-capture detector (GC/ECD). Skarping et al.\(^{(204)}\) reported that aromatic amines could be separated as their perfluoro fatty acid

---

**Figure 5** Gas chromatograms obtained from benzenesulfonyl derivatives of (a) primary and (b) secondary amines. GC conditions: column, DB-1 (15 m × 0.53 mm i.d.); column temperature, programmed from 120 to 280°C at 10°C min\(^{-1}\); injection and detector temperatures, 290°C; nitrogen flow-rate, 10 mL min\(^{-1}\); detector, FPD (S mode). Each peak corresponds to 2 ng of amine. Peaks: 1 = methylamine; 2 = ethylamine; 3 = isopropylamine; 4 = $n$-propylamine; 5 = isobutylamine; 6 = $n$-butylamine; 7 = isoamylamine; 8 = $n$-amylamine; 9 = hexylamine; 10 = cyclohexylamine; 11 = heptylamine; 12 = benzylamine; 13 = octylamine; 14 = $\beta$-phenylethylamine; 15 = dimethylamine; 16 = diethylamine; 17 = dipropylamine; 18 = pyrrolidine; 19 = morpholine; 20 = piperidine; 21 = dibutylamine; 22 = hexamethyleneimine; 23 = N-methylbenzylamine. 2.5 Chemiluminescence Detector

The CLD or thermal energy analyzer (TEA), based on emission spectroscopy, is a selective detector for nitroso and nitroaromatic compounds. The response of the TEA to N-nitroso compounds is based on the reaction of nitrogen oxide with ozone combined with the preceding pyrolysis of nitroso compounds. A schematic diagram of a TEA is shown in Figure 10. The eluate from the GC column enters the pyrolyzer where the selective catalytic decomposition of N-nitroso compounds takes place, resulting in a nitrosyl radical and an organic radical. The N—NO bond is the weakest in these compounds. The pyrolyzer eluent expands into the evacuated reaction chamber in which the nitrogen oxide reacts with ozone, resulting in excited nitrogen dioxide. The excited nitrogen dioxide rapidly decays back to its ground state with the characteristic emission of light. Then the emitted radiation is detected by a photomultiplier through a red optical filter. The filter is used to block possible light emission resulting from sources other than NO chemiluminescence. The intensity of the emission is proportional to the nitrosyl radical concentration, and hence to the N-nitroso compound concentration. The decomposition of substances with a catalyst at lower temperatures of
about 300 °C is more advantageous than pyrolysis at elevated temperatures, because the decomposition of the N–NO bond is more selective, even though the detector response to nitrosamines is diminished at lower temperature. The response of the CLD to nitroaromatic compounds increases rapidly with increasing temperature. The response of the CLD to nitrosamines is diminished at lower temperatures, because the decomposition of the NO bond is more selective, even though the detector response to nitrosamines is diminished at lower temperatures.

The CLD has been used as a selective detector for N-nitrosamines and secondary amines by modification of the pyrolyzer C and on-column injection of 2 µL of toluene solution at 115 °C; column temperature, isothermal at 115 °C for 2 min and then programmed from 115 to 300 °C at 10 °C/min and held at 300 °C for 5 min; carrier gas, helium at 0.8 kg cm⁻²; detector, ECD (constant-current mode); make-up gas, argon–methane (95:5) at 55 mL min⁻¹. Each peak corresponding to 20–80 pg of amine. Peaks: 1 = aniline; 2 = 2,6-toluidine; 3 = 2,4-toluidine; 4 = 2,4-diaminoanisole; 5 = α-naphthylamine; 6 = β-naphthylamine; 7 = 4-aminobiphenyl; 8 = 1,5-naphthalenediamine; 9 = benzoidine; 10 = 4,4′-methyleneedianiline; 11 = o-tolidine; 12 = 4,4′-methylenebis(o-chloroaniline); 13 = 4,4′-diamino-3,3′-dimethoxybiphenyl(o-dianisidine). Peaks denoted R refer to reagent and solvent impurities. (Reprinted from G. Skarping, L. Renman, B.E.F. Smith, J. Chromatogr., 267, 315–327 (1983), Copyright 1983, with permission from Elsevier Science.)

2.6 Mass-selective Detector

MSD has been recognized as an excellent detector for GC, because the spectral data provide the qualitative information lacking in other GC detectors. When a molecule in the vapor state is bombarded with electrons,
bonds are ruptured and the molecule ionizes. The kind and amount of fragments obtained are characteristic of the molecule. In a magnetic sector MSD, when the positively charged fragments are accelerated into a magnetic field, they travel curved paths, the radii of which are proportional to the square roots of the masses of the ions. By varying the magnetic field, the segregated ion beams containing ions of identical mass-to-charge ratio are swept successively past a collector. Here, the ions discharged, producing currents proportional to the relative abundances of ions of each mass. These currents are recorded successively to give the mass spectrum. On the other hand, a quadrupole MSD performs a different mass separation, using four rods with an electric field between them. As the ions enter the field, they interact with it in such a way that only ions of a specific mass-to-charge ratio will pass through to the detector. A scan of many ions is achieved by varying the electric field. An ion trap mass detector (ITD) can store the ions of a certain mass in stable paths for many seconds. The ion trap is scanned over a mass range whereby the ions are detected by a conventional electron multiplier. The two most common techniques used to produce ions in an MS are electron impact ionization (EI) and chemical ionization (CI). A schematic diagram of a typical electron impact ionization mass spectrometry (EIMS) system is shown in Figure 12.

An MSD consists of four main parts: ion source, mass analyzer, detector, and instrument control and data-handling computer system. The first step in a GC/MS analysis is qualitative identification, using a complete scan across the entire mass range. Identification can be done with the help of spectral libraries, usually kept in a database on a computer with the detector-controlling software. The molecular ion and characteristic ions are used for the identification of compounds. The second step is quantitative analysis using SIM. By using a filter to select only a few ions, the sensitivity can be increased. The final step is the total ion chromatogram (TIC), based on the plot of total response (sum of all ions) over time by scanning repeatedly. For quantitative SIM analysis, it is necessary first to accomplish the optimum chromatography, select ions which are compound specific (molecular ion or fragment ion), give a large signal and have no interferences. Next it is necessary to

Figure 10 Schematic diagram of a TEA.

Figure 12 Schematic diagram of a typical mass spectrometer with an electron-impact ion source.

optimize the MSD response to the monitored ions, calibrate each ion mass and assign the dwell time for each ion using GC peak width and ion signal ratios.

GC/MS can provide structural information for the unequivocal identification of amines and can be applied to the analyses of various amines such as aliphatic and aromatic amines, N-nitrosamines and heterocyclic amines. Aliphatic amines are analyzed after derivatization with pentafluorobenzaldehyde (PFBA). Sacher et al. reported that aliphatic primary and secondary amines could be determined as their N-benzenesulfonyl and 2,4-dinitrophenyl derivatives (Figure 13a and b) and the method using the former derivatives was more selective and sensitive. Longo and Cavallaro developed a method for the simultaneous identification of 73 primary and secondary aromatic amines as their heptafluorobutyramides. (Figure 14) The electrophoretic derivatives were analyzed by GC combined with an ECNICI MSD. Detection limits of these amines were in the range 0.3–66.3 pg injected in the full-scan mode and 0.01–0.57 pg injected in the SIM mode. Furthermore, Skog et al. analyzed six nonpolar heterocyclic amines by GC/MS in the SIM mode. Murray et al. developed a sensitive and selective method for the determination of several heterocyclic amines as their 3,5-bistrifluoromethylbenzyl derivatives by negative-ion chemical ionization mass spectrometry (NICIMS) in the SIM mode. The detection limits were 1 pg.

2.7 Electrolytic Conductivity Detector

The ELCD is a useful detector in environmental analysis owing to its selectivity for halogen-, sulfur- and nitrogen-containing compounds. This is done by mixing the effluent with a reaction gas (oxidizing or reducing) in a reaction catalyst (usually nickel). The resulting gas-phase reaction products are then combined with a stream of deionized solvent, producing a conductive solution. The electrical conductivity of the liquid is measured and recorded. In the case of nitrogen-mode analysis, the column eluate is reduced with H₂ at 800–900°C in a nickel reaction tube, producing ammonia by the decomposition of organic nitrogen compounds. Under these conditions, the organic halogen, sulfur, oxygen and phosphorus compounds are converted into HX, H₂S, H₂O, PH₃ and lower alkanes. Although H₂S and lower alkanes (mainly methane) give a low response owing to the low ionization, the acidic products can be removed with a basic scrubber placed between the reaction chamber and the conductivity cell.
Ammonia is the only base formed during the reductive catalytic decomposition of the organic compounds. This gaseous product is then dissolved in HCl–ethanol and the change in solvent conductivity is measured. Therefore, other reduction products do not cause an increase in conductivity in this solvent. The carrier gas and hydrogen reducing gas must be very pure for noise-free, sensitive operation. The solvent is conditioned in an ion-exchange resin to maintain conductivity. Although the selectivity depends on the compound and element, the selectivity ratios for the detection of nitrogen and halogen compounds versus carbon detection are $10^4$–$10^6$ : 1 and $10^3$ : 1, respectively. The sensitivity of the ELCD to chlorinated compounds is about 0.1–1 pg. Whereas the solvent used in analysis with an ELCD can be of liquid chromatographic grade, the gas flow system must be kept very clean. Carbon particles in the conductivity cell can cause spiking and noise, as can a used or dirty nickel reaction tube.

The ELCD has been applied to the analyses of several amines. Riggin et al. evaluated some selective GC detectors, such as the NPD, ELCD and photoionization detector (PID), for the analysis of aniline compounds. PID can detect components which are ionized by an ultraviolet (UV) light source. The NPD and ELCD gave similar detection limits, although the NPD gave a more stable baseline and less day-to-day variation in response. On the other hand, the PID gave a lower response, although the detection limits were improved by using a higher energy source.

### 3 APPLICATION IN ENVIRONMENTAL ANALYSIS

#### 3.1 General Techniques for Sample Preparation

Amines are present in the environment at low parts per billion levels or less. When environmental samples are analyzed by GC with a nonselective detector such as an FID, many peaks with the same retention times as those of amines are often present in the chromatograms. Although GC analyses with selective detectors can
save sample preparation, a cleanup procedure for the complex sample matrix is necessary for the reliable and accurate analysis of amines. In order to remove co-eluting interferences and to preconcentrate amines, the extraction and cleanup of the sample have been performed using a number of different purification techniques, such as distillation, liquid–liquid extraction, adsorption with various adsorbent tubes or columns, preparative high-performance liquid chromatography (HPLC), solid-phase extraction (SPE) with various cartridges and solid-phase microextraction (SPME). Some amines can be separated by acid–base partitioning, because these compounds can be extracted with organic solvents not at low pH (<1), but at high pH (>10). Adsorption with an adsorbent tube or column is effective for the separation of amines, but it is time-consuming. Blue-cotton, blue-rayon, blue-chitin, cotton, rayon or chitin bearing covalently linked copper phthalocyanine trisulfonate as a ligand can selectively adsorb secondary amines and other mutagens/carcinogens having polycyclic planar molecular structures. Normal- or reversed-phase HPLC fractionations are also useful for sample preparation. SPE is simple and rapid, and good recoveries of amines are obtained. SPME, recently developed by Pawliszyn, is an extraction technique using a fused-silica fiber that is coated outside with an appropriate stationary phase, and saves preparation time, solvent purchase and disposal costs, and can improve the detection limits. It has been used routinely in combination with GC and GC/MS and has been successfully applied to a wide variety of compounds, including amines.

3.2 Aliphatic Amines

GC methods for the determination of aliphatic amines using selective detectors have been applied to various environmental samples such as air, cigarette smoke, water and soil. Many of these methods have been used for free amines, and the trace analysis of low-molecular-mass aliphatic amines in air has been performed with nitrogen-selective detectors such as NPD, CLD and GC/MS types by direct injection or the headspace technique. Derivatization methods have also been used with water and soil samples, because these samples cannot be analyzed directly. Kuwata et al. analyzed low-molecular-mass aliphatic amines in air samples in and around livestock houses by Sep-Pak C18 cartridge treatment and subsequent GC with thermionic detection, and detected methylvamine (0–12.4 ppb) and trimethylamine (0.28–69.7 ppb) (Figure 2b and c). Gronberg et al. developed a method for the determination of short-chain aliphatic amines in ambient air based on impinger sampling in dilute H2SO4, selective enrichment across a polytetrafluoroethylene (PTFE) gas membrane and quantification by gas chromatography/thermionic specific detection (GC/TSD). The enrichment step was carried out in a flow system directly connected to the GC column and methylv-, dimethyl-, trimethyl-, diethyl- and triethylamine were detected at the parts per trillion level. Kataoka et al. reported the determination of secondary amines as their N-diethylthiophosphoryl derivatives in cigarette smoke by gas chromatography/flame photometric detector (GC/FPD). This method is selective and sensitive to secondary amines, and the detection limits of amines are 0.05–0.2 pmol. By using this method, it was confirmed that dimethylamine, pyrrolidine, piperidine and morpholine occur in main- and side-stream smokes of cigarettes, and the contents of these amines in side-stream smoke are very high compared with those in main-stream smoke. Kashihiira et al. analyzed trimethylamine in freezer air by GC/CLD after preconcentration with a Tenax-GC® tube, and detected 2.4 ppb of trimethylamine. Koga et al. reported the determination of trace amounts of 12 aliphatic primary and secondary amines as their dinitrophenyl derivatives in waters from sewage and river by GC/MS. By using this method, low-molecular-mass aliphatic amines in water samples can be determined in the range 1–3 ppb. Avery and Junk reported the determination of trace amounts of seven aliphatic primary amines in waters from tap, river and oil shale process by GC/MS based on Schiff base formation with PFBA. This method is specific for primary amines and the detection limit is 10 ppb with no sample transfers or manipulations being necessary for sample volumes of 0.5 mL. Terashi et al. reported the determination of eight primary and secondary amines in river water, seawater and sea sediment by GC/MS in the SIM mode based on distillation of the sample under alkaline conditions and subsequent benzenesulfonfylation. In this method, the detection limits of amines in water and sediment are 0.02–2 and 0.5–50 ppm, respectively. Pietsch et al. analyzed aliphatic and alicyclic amines in wastewater samples by GC/MS after derivatization with trichloroethyl chloroformate and liquid–liquid extraction, and detected morpholine and piperidine. Sacher et al. analyzed primary and secondary amines in industrial wastewater and surface water samples by GC/MS as their N-benzenesulfonaryl derivatives, and detected methylvamine, dimethylamine, morpholine and ethanalamine in concentrations up to 100 µg L–1. Furthermore, ethylvamine and diethylamine were found in concentrations up to 30 µg L–1. Tsukioka et al. reported the determination of lower aliphatic tertiary amines in pond water and bottom sediments (Figure 15a–c). These amines were determined by headspace GC/MS in the SIM mode...
Figure 15 SIM chromatograms of standard aliphatic amines and environmental samples. (a) Standard aliphatic amines; (b) pond water from Suwa Lake; (c) bottom sediment from Tokyo Bay. GC/MS conditions: GC column, TC-1 (30 m × 0.53 mm i.d.); column temperature, initially 40°C for 2 min, increased to 180°C at 20°C/min and held at 180°C for 5 min; injection temperature, 180°C; separator and ion source temperatures, 250°C; ionization voltage, 70 eV; carrier gas, helium at 75 cm³ s⁻¹. Peaks: 1 = trimethylamine; 2 = triethylamine-d₅; 3 = triethylamine; 4 = triallylamine; 5 = tripropylamine; 6 = tributylamine. (Reprinted from T. Tsukioka, H. Ozawa, T. Murakami, J. Chromatogr., 642, 395–400 (1993), Copyright 1993, with permission from Elsevier Science.)
after distillation. The detection limits for the final 40-mL samples were 5–50 ng and this method showed excellent sensitivity and selectivity.

### 3.3 Aromatic Amines

GC methods for the determination of aromatic amines using selective detectors have been applied to various environmental samples such as air, 

- cigarette smoke (25,53) wastewater (31–34) and soil. (55) Beker (19) reported the determination of several aromatic amines in workplace atmosphere by gas chromatography/nitrogen–phosphorus detector (GC/NPD). Air samples are collected in three-section silica gel tubes and the amines on silica gel are eluted with 2-butanone. Garcia-Valcarcel et al. (55) determined several dinitroaniline herbicides in environmental samples by GC/NPD after solvent extraction. Schmidt et al. (33) reported a method for the selective determination of aromatic amines in water samples. This method is based on the SPE at pH 9, subsequent derivatization to the corresponding iodobenzenes and GC/ECD analysis. Aniline and nitroaniline compounds were detected in groundwater samples (Figure 16). Pieraccini et al. (25,53) reported the determination of 17 primary aromatic amines as their pentafluoropropionamides in cigarette smoke and indoor air by GC/MS in the SIM mode. Cigarettes are smoked in a laboratory-made smoking machine and the amines in the main- and side-stream smokes are trapped in dilute hydrochloric acid. It is confirmed that side-stream smoke contains total levels of aromatic amines about 50–60 times higher than those in main-stream smoke, and some aromatic amines in ambient air such as offices and houses may be derived from considerable contamination of aromatic amines in side-stream smoke. Kataoka et al. (50) analyzed aromatic amines in the cigarette smoke samples as their N-n-propoxycarbonyl derivatives (Figure 3b) and their N-dimethylthiophosphoryl derivatives by GC/NPD and GC/FPD (P mode), respectively, after collection of smoke samples in the same manner. Okumura et al. (45) determined aniline and related aromatic amines in river water and sediment samples by GC/MS in the SIM mode after liquid–liquid extraction and steam distillation. The detection limits of the anilines in water and sediment samples were 4.2–31 pg mL$^{-1}$ and 1.2–4.0 ng mL$^{-1}$, respectively. Longo and Cavallaro (46) analyzed aromatic amines in groundwater samples as their heptafluorobutyroyl derivatives by gas chromatography/electron-capture negative-ion chemical ionization mass spectrometry (GC/ECNICIMS) after concentration with a Kuderna–Danish evaporator. Muller et al. (47,48) reported the determination of aromatic amines by SPME and GC/MS. This method was simple, rapid, precise and sensitive and various groundwater samples could be directly analyzed (Figure 17a and b). Guan et al. (35) also analyzed nitroaniline herbicides in river water by SPME and GC/ECD.

#### Figure 16 GC/ECD of a groundwater from Stadtallendorf. GC conditions and peak numbers as in Figure 9. (Reprinted from T.C. Schmidt, M. Less, R. Haas, E. von Low, K. Steinbach, G. Stork, J. Chromatogr. A. 810, 161–172 (1998), Copyright 1998, with permission from Elsevier Science.)

### 3.4 N-Nitrosamines

GC determinations of N-nitrosamines in environmental samples have been carried out in indoor and outdoor air, (94,95) combustion smoke, (52,82,96–103) water, (104–107) rubber products, (111–118) metalworking fluids, (120) drug formulations, (121,122) and agricultural chemical formulations, (110,123,124) In most of them, N-nitrosamines are directly analyzed as the free form by GC/TEA, based on the detection of the chemiluminescence emitted from a reaction between releasable NO radicals and ozone after thermal cleavage of N–NO bond in N-nitroso compounds. Fadlallah et al. (95) determined volatile nitrosamines in the factory environment by GC/TEA (Figure 11b). Air samples were collected by drawing air through a Thermosorb/N cartridge, and then the sorbent was eluted with methanol–dichloromethane (1:3). Brunemann et al. (97–100) analyzed volatile and tobacco-specific N-nitrosamines in main- and side-stream smoke of cigarette and tobacco by GC/TEA. The smoke sample was collected in citrate buffer (pH 4.5) containing 20 mM ascorbic acid and then extracted with dichloromethane. N-Nitrosodimethylamine, N-nitrosopyrrolidine, N-nitrosomethylhydrazine and some tobacco-specific nitrosamines such as N-nitrosornicotine, 4-(methyl-
nitrosamino)-4-(3-pyridyl)butanal and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanoic acid were detected. The \( N \)-nitrosamines in environmental tobacco smoke, to which both smokers and nonsmokers are exposed, have received a great deal of attention as a source of indoor pollution. Tomkins et al.\(^{106,107}\) determined \( N \)-nitrosodimethylamine in drinking water and groundwater at the parts per trillion level by GC/CLD (nitrogen mode) (Figure 18a–c). Furthermore, they developed new sample preparation procedure for the extraction of \( N \)-nitrosamines using a \( C_{18} \) membrane extraction disk. Thompson et al.\(^{114,115}\) reported the determination of \( N \)-nitrosamines in rubber nipples and pacifiers at the parts per billion level by GC/TEA (Figure 19a–c). In these samples, \( N \)-nitrosodibutyramine was the principal \( N \)-nitrosamine found, along with trace amounts of \( N \)-nitrosodimethylamine, \( N \)-nitrosodiethylamine and \( N \)-nitrosopiperidine. The occurrence of \( N \)-nitrosamines in baby bottle rubber nipples and pacifiers is of special concern because traces of these amines may migrate to infant saliva during sucking, and then be ingested. Although GC/TEA can be used as a sensitive and specific method for the analysis of \( N \)-nitroso compounds, it is too expensive to use in many laboratories. As an alternative method, Kataoka et al.\(^{52,96}\) reported the determination of seven \( N \)-nitrosamines by GC/FPD (P mode). The method is based on denitrosation with hydrobromic acid to produce the corresponding secondary amines and subsequent diethylthiophosphorylation of secondary amines. By using this method, it was confirmed that \( N \)-nitrosodimethylamine, \( N \)-nitrosopyrrolidine and \( N \)-nitrosopiperidine occur in mainstream and sidestream smoke of cigarettes. In addition, some \( N \)-nitrosamines in various environmental samples were determined by GC/NPD,\(^{123}\) GC/ECD\(^{120}\) and GC/MS.\(^{103,105,124}\)

3.5 Heterocyclic Amines

Most heterocyclic amines are polar and of low volatility, and tend to elute as broad and tailing peaks owing to strong adsorption on the column and injector during...
GC analysis, when they are analyzed without derivatization. Therefore, the analysis of these amines has been generally carried out by HPLC. For the GC analysis of heterocyclic amines, several derivatizations using acetic anhydride, trifluoroacetic anhydride, HFBA, pentafluorobenzyl bromide, 3,5-bistrifluoromethylbenzyl bromide and 3,5-bistrifluoromethylbenzyl chloride have been tested. However, acylation with acid anhydrides yielded derivatives with very poor GC properties. The alkylation products with pentafluorobenzyl bromide, 3,5-bistrifluoromethylbenzyl bromide and 3,5-bistrifluoromethylbenzyl chloride had good GC properties for some heterocyclic amines. However, these methods gave a mixture of mono- and dialkylated forms and were used for GC/MS analysis but not for GC analysis. Recently, Kato and Kijima developed a simple and rapid derivatization method for the GC analysis of mutagenic heterocyclic amines. Ten heterocyclic amines were converted into their N-dimethylaminomethylene derivatives with N,N-dimethylformamide dimethyl acetal and measured by GC/NPD. As shown in Figure 20(a), these heterocyclic amines were separated within 7 min, although AαC and 2-aminoimidazol[1,2-a:3',2'-d]imidazole (Glup-P-2) co-eluted. The detection limits of these compounds ranged from 2 to 15 pg. By using this method, AαC, 3-amino-1,4-dimethyl-5H-pyrido[3,4-b]indole (Trp-P-1), 3-amino-1-methyl-5H-pyrido[3,4-B]indole (Trp-P-2), 2-amino-6-methylpyridine[1,2-a:3',2'-d]imidazole (Glup-P-1), IQ, 2-amino-3,4-dimethylimidazo[4,5-f]quinoline (MeIQ), and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) were determined in several combustion smoke samples (Figure 20b and c). On the other hand, few GC/MS (SIM mode) data using positive-ion electron ionization and negative-ion CI on the analysis of heterocyclic amines after derivatization are available. Vainiotalo et al. analyzed MeIQx and DiMeIQx in cooking fumes as their 3,5-bistrifluoromethylbenzyl derivatives by GC/MS in the SIM mode (Figure 21a and b). The cooking fumes were collected through a glass-fiber funnel into a sampler which consisted of two glass-fiber filters and an XAD-2 sorbent tube. Although these heterocyclic amines give a mixture of mono- and dialkylated forms and were used for GC/MS analysis. The spectra of the dibistrifluoromethylbenzyl derivatives possess high-mass fragment ions suitable for SIM work. When ions at m/z 438 MeIQx and m/z 452 DiMeIQx were specially monitored, the detection limit of these compounds was 2 pg.

4 CONCLUSIONS

Environmental pollution is recognized as an important problem for public health, because it is very close to the daily life of people throughout the world. The occurrence and toxicity of hazardous chemicals in the biosphere have received a great deal of attention in recent years. Neglect of environmental pollution caused widespread contamination of air, soil and water, unhealthy conditions for workers and the loss of many precious natural resources. Therefore, environmental measurements are essential as a significant index of risk assessment not only in establishing the quantitative relationship between exposure and response to these pollutants, but also in establishing the natural baseline conditions in the...
environment. Toxic amines, described in this article, are widely distributed in a number of ambient environmental components such as air, diesel exhaust, cigarette smoke, cooking fumes, river water, sewage water, soil and chemical products. The presence of these amines in the environment may be more extensive than previously thought and humans are continually exposed to these compounds in normal daily life. Therefore, monitoring of amines in the environment is very important to preserve human health and the natural environment, and practical and reliable methods for determining accurate exposure levels of these amines need to be established. For this purpose, various analytical methods have been developed. In particular, GC is one of the most useful techniques for the simultaneous determination of most amines. However, the amines in environmental samples are generally present at very low concentrations and are often to be found among complex matrices containing a number of co-existing substances. Therefore, GC detectors for environmental analysis must be not only sensitive to minute amounts of analytes, but also selective enough to discriminate against reasonable amounts of co-existing substances.

The nitrogen-selective thermionic detectors, the nitrosamine-specific detector TEA and GC/MS have been widely used for obtaining high sensitivity and selectivity. In addition, conversions of amines into fluorinated derivatives to introduce an ECD response and into sulfur- and phosphorus-containing derivatives to introduce an FPD response have been devised for these purposes.

GC with nitrogen-selective thermionic detection is highly sensitive and selective for amine analysis, and available in most laboratories. Although the selectivity and sensitivity of thermionic detectors depend on the flow rates of hydrogen, air, make-up gas and carrier gas, a relatively stable response is realized using a flameless type of thermionic detector. GC/MS, capable of measuring simultaneously retention time and molecular mass, is a powerful technique for the identification and quantification of amines in complex matrix samples. The TEA is also selective and sensitive for N-nitrosocompounds, but its response depends on the pyrolysis temperature. Although
GC/MS in the SIM mode and GC/TEA are most effective for the analysis of a specified amine, they require sophisticated and expensive equipment that is beyond the reach of many laboratories. GC/FPD and GC/ECD require the derivatization of amines to the corresponding halogen- and sulfur- or phosphorus-containing compounds, respectively, but thereby offer increased selectivity and sensitivity for specific amines. GC methods with selective detectors, described in this article, have advantages and disadvantages and so far there are no all-powerful analytical methods.

The choice of an analytical method depends on the presence of amines in the environment at low parts per billion levels or less and the variety and complexity of the sample. In order to achieve an efficient isolation and preconcentration of amines, several methods of sample preparation for the analysis of various environmental samples have been developed using a number of different purification techniques, such as distillation, liquid–liquid extraction, column chromatography, SPE, extraction with mutagen specific adsorbent and preparative HPLC. The combination of these techniques is used successfully for
Figure 21 GC/MS (SIM mode) traces of (a) fumes from fried beef/pork and (b) a standard sample containing 5 ng of MeIQx, 1.5 ng of 4,8-DiMeIQx and 2.5 ng of 7,8-DiMeIQx. The base peaks of the di-bis-TFMB (trifluoromethylbenzyl) derivatives were monitored (MeIQx, m/z 438; DiMeIQx, m/z 452). GC/MS conditions: column, HP-5 (20 m × 0.2 mm i.d.); column temperature, initially isothermal at 70°C for 1 min, increased to 280°C at 25°C/min and held at 280°C for 5 min; injector temperature, 250°C; carrier gas, helium at 1 mL/min; ionization voltage, 70 eV; emission current, 300 µA. (Reproduced by permission of Springer-Verlag from S. Vainiotalo, K. Matveinen, A. Reunanen, Fresenius’ J. Anal. Chem., 345, 462–466 (1993), Copyright Springer-Verlag.)

the extraction and purification of amines. However, many of these methods are time-consuming, laborious and give low recoveries for some specific amines. On the other hand, the SPME method is simple and rapid, and is directly applicable to the sample.

Environmental analysis has benefited from the recent advances in GC, including high-resolution columns for complex mixtures and improved sensitivity and selectivity in detection. Powerful selective detection tools coupled with the many technological advances in capillary columns, software and hardware over the past decade have added a new dimension. Measurement techniques in environmental analysis will become increasingly more sensitive and selective in the future. For this purpose, further developments in selective GC detectors and in capillary columns, e.g. shorter inactive columns with smaller internal diameters giving ultrahigh column efficiency and speed, higher temperature phases and exterior coating for the fused-silica tubing, will permit the analysis of both high-temperature and highly volatile amines. Furthermore, simple, rapid and automated separation and analysis of compounds in various environmental samples will be achieved by combination with convenient sample preparation techniques such as SPME.

Heavy Metals Analysis in Seawater and Brines
Osvaldo E. Troccoli
University of Buenos Aires, Argentina

1 Introduction

There has been growing concern during and since the 1990s about the effect that the toxicity and persistence of heavy metals will have on the biosphere. Consequently, these new environmental pressures have challenged analysts to find better experimental procedures for handling, recognition and evaluation of traces of heavy metals.

Moreover, the determination of low levels of heavy metals in seawater has received particular attention as a way of assessing the early impact of human activities on the marine environment. It is necessary to protect the marine and continental waters against contamination so as to allow suitable conditions for the maintenance of aquatic life and the various uses derived from aquatic life.

It is not the metal concentration alone that enables an environmental diagnosis to be made but the way metal combines with other elements to form species. These species are responsible for the biological behavior of the heavy metal under consideration, as its bioavailability will determine the amount of harm it may cause. Thus, “speciation” studies should be conducted to assess the potential environmental impact of human activities.

From the analytical point of view, seawater and brines may be considered to be closely related systems in terms of matrix effects and analytical difficulties. Hence these two systems will be included in this article although the aims of heavy metal detection and determination might be diverse in each case.

Analytical inaccuracies that arise from the high salt content of the seawater or brine solutions are exacerbated by the low levels of trace metals, which require careful control of contamination during sample collection and analysis and very sensitive analytical techniques.

Different techniques for the determination of trace metals in seawater, such as spectroscopic and electroanalytical methods, will be discussed here in terms of their performance in dealing with the problem of trace metal detection and determination.

Even the term “trace” has had different meanings over the years, normally being associated with the detection limit of the technique employed (“traces”, “footprints” or “trails” have a lot to do with the way they are observed). Amounts that would have been considered traces in the 1960s are probably no longer considered as such in the 1990s, as detection limits for most heavy metals have been lowered by three to six orders of magnitude (using “state of the art” techniques) since the late 1960s.

Special attention has been paid to the preconcentration of the analyte and its isolation from the matrix constituents which might obscure its accurate determination. A variety of separation–preconcentration methods will be presented, with a strong bias towards those procedures leading to some kind of automation, because pretreatment of the samples is often time-consuming and prone to contamination and may lead to an incomplete recovery of the analytes.

Flow injection analysis (FIA) has appeared as a solution to time-consuming and complicated separations and it will also be discussed in relation to alternative forms of analysis, especially in terms of its ability to perform speciation studies.

1 Introduction

Interest in the determination of heavy metals at trace levels in seawater derives from the importance that has been placed on the study of the fate of accumulative toxins in nature.

Marine chemistry, marine biology, geochemistry, and environmental science researchers are interested in the horizontal, vertical, and seasonal distribution of trace metals in seawater, as well as in trace metal biochemical and geochemical cycles in the ocean. Moreover, the determination of low levels of heavy metals in seawater has received particular attention as a way of assessing the early impact of human activities on...
the marine environment, as a necessary preliminary to protecting marine and continental waters against contamination so as to allow suitable conditions for the maintenance of aquatic life and the various uses derived from it.

Most coastal nations have passed regulations in order to assess and control the contamination of their marine waters. To illustrate the importance that has been given to this issue, European Community Directives on the quality of continental and marine waters should be consulted: for marine ecosystems European Directive 79/923/CEE\(^1\) limits the levels of Ag, As, Cd, Cr, Cu, Hg, Ni, Pb and Zn in seawater used to keep molluscs.

Knowledge of the metal concentration, together with the way it is combined with other elements to form species, enables an environmental diagnosis to be made. These species are responsible for the biological behavior of the heavy metal under consideration, as its bioavailability will determine the amount of harm it may cause. Thus, “speciation” studies should be conducted to assess the potential environmental impact of human activities.

From the analytical point of view, seawater and brines may be considered to be closely related systems in terms of matrix effects and analytical difficulties. Hence these two systems will be included in this article although the aims of heavy metal detection and determination might be diverse in each case.

Analytical inaccuracies that arise from the high salt content of the seawater or brine solutions are exacerbated by the low levels of trace metals, which require careful control of contamination during sample collection and analysis and very sensitive analytical techniques.

Different techniques for the determination of trace metals in seawater, such as spectroscopic and electroanalytical methods will be discussed here in terms of their performance in dealing with the problem of trace metal detection and determination.

High salinity and complex chemical composition of seawater and brines, together with a very low concentration level for the heavy metals, are the main obstacles to their proper analysis. Special attention has been paid to the preconcentration of the analyte and its isolation from the matrix constituents which might obscure its accurate determination. A variety of separation–preconcentration methods will be presented, with a strong bias towards those procedures leading to some kind of automation, because pretreatment of the samples is often time-consuming and prone to contamination and may lead to an incomplete recovery of the analytes.

FIA has appeared as a solution to time-consuming and complicated separations\(^2\) and it will also be discussed in relation to alternative forms of analysis, especially in terms of its ability to perform speciation studies.

2 ANALYTICAL CHEMISTRY OF HEAVY METALS

2.1 Challenges Posed by the Ever-increasing Need to Improve Detection Limits

The identification and quantitation of heavy metals at trace levels has been widely studied and several books are available for consultation.\(^3–5\)

Concern about the effects of the toxicity and persistence of heavy metals on the biosphere is growing. These new environmental concerns have challenged analysts to find better experimental procedures for handling, recognition and evaluation of traces of heavy metals.

What is meant by “better experimental procedures”? This is a difficult question to answer, because it depends on the purpose of the trace determination, which might be classified by the following:

- precise concentration determination
- concentration profiles assessment
- bioavailability determination.

Precise concentration determination should be understood as a means of selecting those operations that pursue the highest accuracy and reproducibility for a single set of measurements. This case is the most frequently used in the development of new techniques, where interest is focused on finding novel ways of improving the features of merit of the technique.

Concentration profiles assessment here refers to operations that obtain information through analysis of a large number of sets of samples taken at different locations at different times. In this case, a new feature of merit, analysis frequency, which will reflect the quantity of reliable data obtained per unit time should be added.

Finally, bioavailability determination is one of the most recent requirements of the analytical chemist involving knowledge of the chemical form in which the analyte is present in the sample.

Here, the chemical “species” is the object of the analysis, and the features of merit will be referred to each species involved, because the toxicity of the heavy metals is related to the way that they could be introduced into living organisms (i.e. as the “chemical species”).

Each of these alternatives may present the analyst with the need to use a different approach, from the evaluation of a large number of samples in a short period of time, to the accurate measurement of a single set of samples or the establishment of the chemical form in which the trace metal is encountered. Even the term “trace” has had different meanings over the years, normally being associated with the detection limit of the technique employed (“traces”, “footprints” or “trails” have a lot to do with the way they are observed). Amounts that would
have been considered traces in the 1960s are probably no longer considered as such in the 1990s, as detection limits for most heavy metals have been lowered by three to six orders of magnitude (using “state of the art” techniques) since the late 1960s.

In the early 1960s, the rise in the use of atomic absorption spectrometry (AAS) and the decline of atomic emission spectrometry (AES) produced a variety of studies using flames as “atom cells” to reveal the potential of this novel technique when compared with prevailing trace analysis techniques.

The average limit of detection (LOD) by that time was in the order of the parts per million for the refractory elements and around the parts per billion range for the easily atomized metals (Zn, Cd). It should be emphasized that the term “LOD” used then corresponded strictly to an instrumental LOD, while this concept was later changed to the expression “methodological limit of detection” (MLD). The MLD reflects more closely the environment of “real” samples than does the LOD, which reflects the instrument performance, usually expressed against a solvent blank and tending to enhance the value of the instrumental technique. (According to IUPAC (International Union of Pure and Applied Chemistry) definitions, LOD is the concentration that produces a signal equal to three times the standard deviation of the blank signal, after a number of determinations of that blank. This LOD is essentially instrumental and should not be confused with the MLD which is defined as the minimum concentration that can be reported as different from zero at a 99% confidence level. The sample containing the analyte whose MLD is being assessed should be compared to a blank that should be clearly defined and that has undergone the same analytical procedure as the sample.)

In the field of the electroanalytical techniques, stripping analysis over Hg (mainly anodic) appeared to be a promising technique for the easily reducible metals, even considering that anodic stripping voltammetry (ASV) is prone to interference when high ionic strength solutions are used.

Later, spectroscopists developed a new atom cell, the electrothermal atomizer (ETA), which improved detection limits several times when background interferences were handled properly, while new electroanalytical procedures derived from stripping analysis become more popular as most of the inconveniences of the former ASV diminished or were eliminated.

The use of inductively coupled plasmas (ICPs) as atom cells introduced a new dimension to metal trace analysis, as detection limits were lowered by two or three orders according to the detection mode selected: inductively coupled plasma/optical emission spectrometry (ICP/OES) or inductively coupled plasma mass spectrometry (ICPMS).

The evolution of the detection limits for some heavy metals may be summarized as follows.

2.1.1 Spectroscopic Methods

In most cases, improvements in detection limits can be associated with the development of new instruments that enhance the signal-to-noise ratio via digital handling of the output signal or by coupling the atomic cell to newly developed detectors like mass spectrometers, or through the development of new on-line analytical procedures that improve the MLD. This becomes evident when observing the evolution of the detection limit for the same metal and technique over the years. FAES (flame atomic emission spectrometry) limits were enhanced when ICP excitation was available, although the excited species might not be the same. Flame atomic absorption spectrometry (FAAS) limits remained almost constant or, in other words, they did not follow the evolution of the electronics and data handling procedures as it would have been reasonable to predict, the explanation being that AAS signals are relative and do not depend so strongly on sensitivity and noise reduction procedures.

The real improvement in AAS MLDs was obtained when the flame atomic cell, continuously fed by spray chamber nebulizers, was replaced by discrete atomizers (mainly ETA) where the atomic cloud is confined giving rise to transient signals which are easily amplified and integrated.

Several important factors should be mentioned when discussing the enhanced sensitivity obtained over the years for electrothermal atomic absorption spectrometry (ETAAS):

1. The use of chemical modifiers: the introduction of a chemical reagent (called the modifier) in excess with respect to the solution to be measured by graphite furnace atomic absorption spectrometry (GFAAS), has proved efficient in converting the analyte element into a phase of higher volatility and/or in increasing the volatility of concomitants.

2. Atomizer development has taken place through the introduction of new atomizing platforms as already mentioned, new atomizer materials like W or Mo, and new ways of heating as transverse heating.

3. New background correction systems have been used.

Finally some of the improvements found in ICP/OES could be ascribed to new sample introduction systems, together with enhanced data handling capabilities.
2.1.2 Electroanalytical Methods

Although acquisition of data for these methods is hindered by the different nomenclatures, it could be said that the enhancement in LODs produced over the years is a consequence of improved data acquisition and data treatment devices. However, it is important to point out that stripping techniques allow better MLDs because the electrolysis time can be managed.

2.2 Preconcentration and Speciation

2.2.1 Preconcentration

The nature of the matrix in which the trace metal is embedded might, however, also condition the analytical performance of the procedure developed. As mentioned earlier, what makes heavy metals analysis in seawater or brines so difficult is the low level in which heavy metals are usually found in these media and the highly saline matrix that contributes to a worsening of the detection performance.

Matrix elimination, sample pretreatment, or simply sample introduction, have been problematic issues in most heavy metals determination techniques, where accurate analyses are sought. No matter which instrumental device is used for the detection, saline samples will generally need special treatment before the analyte reaches the detection stage.

In any case, even if the lowest detection limits were achieved, some of the heavy metals present in seawater or brines cannot be quantified because their concentration levels in those matrices are below the LOD attainable, and some way of increasing their concentrations needs to be used in order to obtain a signal that is at least ten times greater than the standard deviation of ten replicates of the blank.

The set of operations performed with the aim of increasing the analyte concentration is usually referred to as "preconcentration", and it has become a discipline of interest among the analytical procedures for trace analysis. Again, available "batch" preconcentration methods have evolved from macro- or semimicroscale solvent extraction or ionic exchange to microscale "on-line" operations.

Preconcentration steps could be classified according to the phase equilibria involved:

1. solvent extraction
2. ion exchange
3. adsorption methods.

These procedures, or a combination of them, have been applied to seawater and brines. Some of the published studies are summarized in Table 1.

Usually, highly saline matrices require a conditioning step to eliminate or diminish the concentration of the salts that cause interference. This conditioning step might also act as a preconcentration step, and the detection device will dictate the extent of conditioning needed, as shown later.

As can be observed in Table 1, preconcentration is often performed using ion-exchange resins, including the so-called "chelating" resins in which the functional group complexes the analyte. These have been included in this group as the final process will be ionic exchange in both resin types. Chelating resins will behave more selectively than plain ionic exchange resins, as a covalent complex is formed between the metal atom and the donor atoms of the ligand (i.e. O, N, S); furthermore, these complexes will be less prone to the influence of ionic strength which seriously affects electrostatic interactions like those observed in ordinary ionic exchange resins. This allows the use of deionized water prepared standards even when measuring seawater samples. Specially prepared fillings combining an inert support like silica with an organic ligand, like oxine derivatives, have also been employed, their selectivity and rigidity (they do not swell like the 100% organic polymers) being their main advantage. However, commercial chelating resins like Chelex 100 might be used with minor mechanical adjustments to compensate for the characteristic swelling. More recently strongly cross-linked resins like Muromac have been employed with good results in terms of selectivity and diminished swelling characteristics, but on-line operation with these resins might be severely impaired due to the low diffusion rate of the metal ions into the resin which in terms affects the chelating velocity.

The choice between batch and on-line operation will depend on several practical considerations, with cost being one of the major issues to be taken into account. Most operations can be performed off-line and the samples can then be processed rapidly, making this approach competitive with on-line processing in terms of time employed, although the probability of contamination or analyte losses is still a serious drawback.

Commercial instruments can be fitted with automatic sampling devices capable of handling hundreds of vials in which samples, standards and blanks may be placed. Later, associated software will perform the necessary operations to calibrate and measure the analyte concentration in each sample.

This automation is particularly useful when multielemental detection systems (typically ICP/OES or ICPMS) that present such advantage over single-element on-line systems (typically HG/AAS, or GFAAS) are used.

Since it was first introduced by Ruzicka and Hansen in 1975 the FIA, which involves the introduction

of a known volume of a liquid sample into a flowing unsegmented liquid carrier, where it is transported to a detector for measurement, has gone a long way in analytical chemistry towards becoming one of the "established" techniques of sample analysis and online sample treatment. FIA has gained acceptance as a powerful tool for rapid, accurate and economic performance of repetitive determinations. In this sense, and as will be shown later, most analytical procedures needed in the determination of heavy metals in seawater and brine require preconditioning and preconcentration steps which can be achieved using FIA.

FIA operations may be performed with the aid of a very simple and economic device, the FIA manifold, which consists typically of a propulsion unit (a peristaltic pump), a sample introduction device (a rotary injection valve), a reaction unit (a piece of tubing and/or complementary device), and a detector.

Continuous-flow processes like FIA enjoy a flexibility that makes them suitable for performing most of the tasks associated with automation in the laboratory and obtaining the benefits of automation: an increase in the reliability (precision) of analytical operations; a reduction in the analysis time dedicated to routine operations; and a more efficient utilization of chemicals.

One of the major goals of FIA has been redefinition of the operational analytical scale on a micro basis, where volumes in the range of microliters are dealt with and consequently there are important savings in chemicals and waste is reduced to a minimum. Moreover, the miniaturization of FIA systems has led to a substantial reduction in the "idle" time between consecutive sample
2.2.2 Speciation

Metal speciation could be broadly defined as the study of the “distribution of the metals over distinct molecular binding forms”\footnote{1} regardless of the effects on the biota that these molecular bindings might have, or it can be focused specifically on the impact on living organisms of these molecular forms. In either case there is a need to isolate the signals produced by those forms in order to establish the composition of the system. This isolation may be performed in situ on-line and continuously or before the detection step.

In natural systems the “molecular form” involved must be defined or characterized because natural molecules are too complex to be defined exactly. It is generally accepted that molecular size together with compound solubility are the most important parameters to be taken into account where the bioavailability of metals is concerned, and an operational or behavioral classification is often preferred to the plain chemical classification.

Del Castilho\footnote{49} clearly illustrates the operational definition through its application to dissolved and particulated matter in seawater, referring to the passage of the sample through a 0.45-µm pore filter to distinguish between dissolved (the fraction that goes through the filter) and particulate bound matter (the fraction deposited on the filter), leaving colloidal complexes in the soluble fraction.

Easily bioavailable metals will probably be found in the soluble fraction, while the insoluble fraction contains particles that will encounter a certain resistance to passing through cellular membranes. Furthermore, even the soluble fraction may need metal to dissociate from its binding particles before going through a successful diffusion process in order to enter the cell. Thus, molecular size determination will be needed on the insoluble fraction and some kind of dissociation behavior should be determined on the soluble fraction.

Bearing in mind both needs, speciation studies should lead to the determination of either the size of the substituents and/or the dissociation rate of the compounds likely to exist, together with characterization of the diffusion pattern of the heavy metals into the cellular membrane.

Several approaches have been used to achieve this purpose. These include previous separation of different molecular forms with the aid of on-line separative devices, like high-performance liquid chromatography (HPLC) and gas–liquid chromatography (GLC) in all their varieties, and operational characterization by means of differential pulse anodic stripping voltammetry (DPASV) and the time of contact concept. Redox speciation might be considered to be a special case of the soluble fraction speciation, provided the species belong to the soluble fraction. However, detailed knowledge of the distribution of oxidation states for a given metal may provide a useful probe of the redox conditions prevailing in the environment.

Some speciation studies performed on seawater are summarized in Table 2.

It must be emphasized that when “total metal” detectors are used (mainly spectroscopic) a previous separation stage is mandatory to achieve some kind of speciation. On the other hand, electroanalytical techniques, under special conditions, might perform speciation without previous separation, as most reduction

2.3 Interferences Most Commonly Encountered in Seawater and Brines

Tables 3 and 4 show the average composition for seawater with a salinity of 35 (inorganic constituents) and the most common organic compounds found for this seawater.

Taking into account the average seawater composition, one may predict that the most common interferences will be the chlorides and sulfates of the alkali and alkaline earth metals, and although it would not be evident at a glance, the organics that might form complexes with the heavy metals. However, these components will not always affect the measurements to the same extent, as interferences are closely related to the detection device employed.

Some facts about the chemistry of highly saline solutions must be remembered, particularly the tendency to form aggregates or compounds with the alkaline chlor-ides, or even the presence of the alkaline chloride, which may hinder the behavior of the trace metal, or physicochemical phenomena associated with high ionic strength solutions. Most natural or artificial brines will fall into the same category in terms of interference. Organic matter will affect the available heavy metal concentration, giving rise to the speciation studies. The interferences associated with each detection technique will be discussed later.

Sources of interference other than the matrix itself are the reactives that have to be used in the conditioning or preconcentration steps. This is particularly true for preconcentration systems in which the preconcentration factor is high and the reactives were used prior to this stage and are difficult to purify (i.e. conditioning with ethylenediamine tetraacetic acid (EDTA) or sodium salts). It is often necessary to pass the reagents through purification steps to ensure an appropriate level of impurities in the sample under consideration.

### 3 Spectroscopic Techniques Applied to Seawater Analysis

3.1 Atomic Spectroscopies

Atomic spectra are unique in that, given the appropriate conditioning and instrumentation, the signals can be assigned univocally to a single element, making the spectroscopic techniques highly specific. Interelement interferences are seldom encountered provided the operation is conducted properly. This, together with the economy of operation, is responsible for the vast usage and popularity of atomic spectroscopies in their two main modes of operation, emission and absorption, and also, but to a lesser extent, fluorescence.

The use of flames as the traditional atomic source has receded with the introduction of novel ways of producing atomic vapors such as ETA, cold vapor generators, laser excitation probes or atmospheric pressure plasmas (ICP or direct current (DC) plasma) and so on, but although these new atom sources have many advantages, there are still thousands of flame-based spectrometers in operation.

3.1.1 Atomic Absorption Spectrometry

During the 1990s, ETA and to a lesser extent cold vapor generators, hydride generators and flames (in that order) have been used as atomic sources in atomic absorption studies on seawater and brines.
Some of the latest studies using flame atomization are summarized in Table 5.

A quick look at Table 5 indicates that preconcentration procedures together with conditioning of the samples have been the objective of most FAAS studies related to heavy metal determination in seawater. No direct determinations are mentioned as a result of the poor LODs obtained.

The spectral interference caused by sodium chloride absorption bands is one of the most important drawbacks of ETAAS applied to seawater analysis. Background correction has proved useful but it still is not a solution to the problem for all the elements. Special devices such as Zeeman effect or Smith–Hiltje background correctors are needed when a deuterium lamp background corrector does not suffice, owing to the structured nature of the sodium chloride absorption spectra. Moreover, vaporization of the analyte is also impaired by the massive amounts of salts present in the sample.

Table 6 shows similar compendia for ETA, mainly GF and related techniques.

Again, it can be seen that preconditioning of the sample has a major role in most of the studies presented, although several papers are devoted to direct determination of the heavy metals, indicating that for some of them the actual LOD are good enough to render direct determination possible or that the metal concentration in those seawater samples is high enough to reach the existing LOD.

Several papers show the interest in coupling different automatic or semi-automatic sampling devices in order to speed up analysis and to enhance its reproducibility, but the discrete nature of the atomization step has made achievement of this quite difficult.

Metals forming volatile compounds, such as hydrides, have been successfully analyzed by AAS or ETAAS. ETAAS is the most sensitive but, at the same time, the most difficult to couple with the HG step due to the discrete nature of both procedures, although hydride trapping has been used to overcome this difficulty. Several studies on this subject are shown in Table 7.

### 3.1.2 Inductively Coupled Plasma as an Atomic Cell, with Emission or Mass Spectrometry Detection

Since their commercial appearance in the 1970s, ICPs as atomic cells have continuously been improved in terms of performance and ease of operation. At the same time, they have become available to more and more laboratories thanks to the decrease in their cost. As a result, ICP is now one of the most promising atomic cells in terms of its efficiency in producing and exciting atomic (or ionic) vapor, which may later be observed by its optical emission (ICP/OES) or by analyzing its mass spectrum (ICPMS).

Table 8 collects together several studies performed using ICP as an atomic cell and different detection devices.

Direct analysis of seawater samples poses a difficult task for ICP atom cells, because the elevated salt content interferes with the proper functioning of the sample introduction system. In this sense, a distinction between sample introduction in ICP/OES and ICPMS should be made. While optical detectors proceed at atmospheric pressure, mass spectrometers work under high vacuum and hence an interface should be provided for operation. Although solutions with a relatively high saline concentration (up to 1% solids) may be employed for operation. Although solutions with a relatively high saline concentration (up to 1% solids) may be employed when using optical detection, in mass spectrometry (MS) instruments these solutions may produce deposition of material on the sampler and skimmer cones and subsequent restriction of the orifices, which in turn will cause a reduction in sensitivity and long-term stability.

Taking into account the nature of the final detection system (photomultiplier tube in ICP/OES and electron multiplier in ICPMS), it could be concluded that the latter would be more efficient than the former as no “photon to electron” transducer interface is needed. The increase in instrumental sensitivity may be over 1000 times for the electron multiplier when compared with the photomultiplier.

The extent and nature of interferences are also a function of the detection system: it was thought that the simplicity of the elemental mass spectra relative to the atomic emission spectra of the elements was an important advantage of ICPMS over ICP/OES. Although

GF, graphite furnace.

not as important as in OES, numerous serious overlaps have been found in ICPMS. It must be emphasized that optical interferences are a result of the complexity of the atomic/ionic spectra, while mass/charge overlappings arise primarily from the generation of molecular species from sample, plasma, and matrix constituents. We cannot alter the atomic spectral complexity of a plasma constituent (we can use high resolution for solving some overlappings), but by changing plasma conditions and plasma chemistry, we can alter the nature of plasma constituents, controlling or eliminating certain spectral interferences in ICPMS.

Several specific sources of spectral interferences can be identified in ICPMS, including basic background species, isobaric or interelement spectral overlaps, analyte species spectral overlaps, and matrix-induced molecular species.
Interelement formation is one of the major drawbacks in MS detection: it is well known that matrix ions generated in the plasma deposit on the interface cones, changing the ionization potential of the plasma and reducing the transport efficiency of the analyte ions into the ion–lens region due to space charge effects. In each case signal suppression results. The combination of these ions with other matrix or plasma ions to form polyatomic interferences has also to be considered when the masses of those compounds lie close to the analyte mass.

This is the case for most heavy metals and the compounds formed between Cl, Br, O, Na, Ca, K, and H present in seawater and N or Ar ions present in the plasma, as can be seen in Table 9.

For these reasons, most of the procedures for seawater analysis begin with a pretreatment step that is used as a preconcentration and matrix-conditioning step at the same time. There are, however, a number of papers dealing with direct determination of heavy metals in seawater\(^\text{(125,137,142)}\) by plain dilution of the samples, taking advantage of the very low LODs obtained with this technique and the relatively high contents of metals in the samples under consideration. It should be mentioned that in some direct determinations ETV was used for the same purpose: the reduction of salt content.

Isotopic dilution techniques, usually employed in radiochemical analysis, have been adapted to MS detection, giving rise to ICP/IDMS systems, that rely for their success on the existence of well-defined and carefully calibrated isotopic mixtures and the possibility of finding noninterferred lines for those analyte isotopes that do not appear in the sample.

### 3.1.3 Atomic Fluorescence Spectrometry

The major drawbacks of AFS for the analysis of heavy metals are the interferences, spectral or chemical, that can exist when analyzing a particular matrix. The former (spectral) are mainly caused by the atom cell design and the presence of molecular fluorescence of matrix concomitants and the latter (chemical) are associated with interactions between the analyte atoms and the matrix compounds either in condensed phase (loss of sensitivity caused by poor atomization) or in vapor phase, where quenching effects are very strong.

Then, obtaining a good LOD means that the concentration of the fluorescence quenching species in the vapor phase is eliminated or diminished and the interelement compounds that might be formed in the atomization step are broken down.

Flames and ICPs provide enough energy to atomize even the refractory elements, but at the same time the population of quenching compounds in those atom cells is high enough to eliminate the fluorescence signal. ETAs, on the other hand, will be free from fluorescence quenching species because no combustion gases will be present, but matrix gases within the furnace atmosphere will present a serious quenching problem.

From the point of view of the spectral source, it should be considered that because fluorescence signals are directly proportional to the spectral line source light intensity, conventional excitation sources like hollow cathode lamps, high-intensity hollow cathode lamps or electrodeless discharge lamps will produce poor excitation and consequently poor LODs while posing geometric limitations to the instrument developer. Lately, laser excitation has been the choice for obtaining the best LOD.

Heavy metal analysis by atomic fluorescence has been confined to a few cases in which the atomization conditions allow good sensitivity. These are described in Table 10.

As can be seen from Table 10, most of the studies performed on seawater by AFS employ a preliminary vaporization step: cold vaporization (Hg), HG (As, Se) or ETV (Ag) in order to “clean” the atomic vapor of interfering compounds and to facilitate the atomization step, avoiding the use of flames. Laser excitation is used when possible.

### 3.2 Other Atomic Spectrometries

#### 3.2.1 X-ray Fluorescence Spectrometry

Few studies have been reported on heavy metal analysis on seawater or brine by X-ray fluorescence spectrometry (XRFS). The reasons for this could be found in the poor sensitivity of this technique and/or the need for cumbersome preconcentration and pretreatment steps. However, some laboratories have succeeded in certification experiments on seawater samples. Table 11 shows the reports found since 1989.

#### 3.2.2 Nuclear Spectrometries

Neutron activation analysis has also scarcely been used for heavy metals determination in seawater or brine. The need for a neutron source or adequate facilities for

4 ELECTROANALYTICAL TECHNIQUES

Electroanalytical procedures have been used for the analysis of heavy metals since the development of conventional (DC) polarography, and they have proved to be reliable methods for water analysis. The ever-increasing need to improve the LOD, as has been stated earlier, has been the driving force in the development of new electroanalytical technologies to improve the sensitivity and selectivity of the detecting devices and new ways to enhance the electroactivity of the sample species.

Technological improvements, focused mainly on the field of sampling and measuring current intensities and potential differences, have changed traditional electrolysis over a mercury drop to more sophisticated ways of observing the same or related phenomena. In this field, the major role played by computer-assisted techniques, under continuous development, that have set new milestones in electrochemical LODs should be stressed.

Voltammetry, based on the current–potential relationship in an electrochemical cell, and particularly with the current–time response of an electrode at a controlled potential, uses the current intensity at that potential as a means of measuring the concentration of the electroactive species.

Considering that the measured current is related to the rate of charge transfer through the electrode–solution interface, and that from an analytical point of view only Faradaic processes contribute to the overall sensitivity of the technique, then all the mechanisms which might enhance either the charge transference or the Faradaic to capacitive current ratio will be welcome. In the same direction, current sampling procedures will provide another means of increasing the sensitivity of the technique. It should be mentioned here that one of the major drawbacks of the electroanalytical techniques is the need to eliminate oxygen from the solutions in order to avoid its interference either as an electroactive substance
HEAVY METALS ANALYSIS IN SEAWATER AND BRINES

or as a competitor for the reduction of the metals at the electrode surface.

Stripping voltammetry, one of the electroanalytical techniques designed to deal with traces of metals, relies on the preconcentration of traces by their electrodeposition over a convenient electrode material (usually mercury) and then the release of the electrodeposited material, with the aid of a potential sweep, while measuring the curve $i$ against $V$.

As the LOD will be a function of the ability to detect the difference between the current obtained with the analyte and the residual current (or blank current), then better results could be expected when reducing the residual current and increasing the sensitivity of the detecting device. Careful selection of the supporting electrolyte is mandatory in order not to add impurities or simply to contaminate the sample, giving rise to a signal superimposed on the analyte’s signal, particularly when measuring current intensities in the nanoampere order.

Voltammetric analysis has been used scarcely in the determination of heavy metals in seawater or brine solutions. The reasons for this can be found in the widespread use of stripping techniques, which are more sensitive than classical voltammetric analysis.

4.1 Stripping Techniques

According to the nature of the species accumulated on the surface of the electrode material and consequently the nature of the potential sweep, different techniques may be described:

V, voltammetry; TTHA, triethylene tetranitrile hexa acetic acid.
1. ASV: the “naked” metals are reduced at the surface of the electrode (and hence accumulated) and then they are reoxidized by a potential sweep and the resulting current is measured.

2. CSV: the metals are complexed with proper ligands and adsorbed on to the electrode surface at a prefixed potential; the complexed metals are then reduced by a potential sweep and the reduction current is measured. This procedure is also known as adsorptive stripping voltammetry’’ (AdSV). The addition of oxidant species may lead to a reoxidation of the complexes during the lifetime of the cycle, giving rise to catalytic adsorptive (cathodic) stripping voltammetry (CAdSV).

It can be said that the principal variables affecting the performance of a voltammetric technique are the electrolysis time, the stirring rate, the electrode area to volume ratio and the mode of the voltage sweep.(167) While the first three account for an improvement in mass transport to the electrode, the last takes into consideration the way the metal ions can be oxidized out of the electrode surface. Novel electrode surface materials, shapes and movements are then added to the previous classification, broadening the panorama of electroanalytical techniques available.

One of the latest developments in the field of the stripping procedures has been potentiometric stripping analysis or potentiometric stripping voltammetry (PSA or PSV): in this case, the system is treated as in ASV until the deposition has been completed; it is then disconnected from the potentiostat and the curve \( V \) versus \( i \) is measured.

Highly saline solutions may be analyzed directly by ASV or CSV provided that the electrolysis time is long enough to accumulate a quantity of analyte great enough to be measured accurately afterwards.

Each of the techniques briefly described above has different capabilities for seawater or brine analysis associated with them. Its high sensitivity, speciation ability, and the use of the matrix (NaCl) as support electrolyte are advantages, while the need for sophisticated equipment or mercury as electrode material (in recession nowadays) is a disadvantage.

Table 13 shows some of the latest studies performed on seawater and brine using electroanalytical procedures.

### 5 COMPARISON OF DIFFERENT APPROACHES

So far we have tried to give a broad panorama of the possible alternatives for the determination of heavy metals in seawater and in brine. Most of the analytical techniques available have been discussed, and a comparison of these alternatives is imperative in order to establish some useful guidelines at the time of choosing the appropriate technique of analysis.

The aims of heavy metal determination are of paramount importance in analyzing alternative procedures. At the beginning of this chapter (section 2.1) we classified the reasons for heavy metal determination into three broad categories, and the procedures for these determinations should be selected in consequence.

Modern analytical chemistry tends to keep the analyte in a “clean environment” reducing handling to a minimum, giving rise to the new breed of hyphenated techniques – those that include a separation step before the detection step. FI techniques have already been used for the determination of most heavy metals in seawater and brine, being employed not only with some of the previously described detection devices, but also with traditional detection systems like fluorometric and spectrophotometric devices.

Table 14 shows some of the latest studies on seawater and brine in which FI techniques have played an important role. This list is by no means exhaustive, as many FI studies have been mentioned before and will not appear in this table; furthermore, with one exception it only covers the 1990s.

The fact that UV/VIS\(^{211–216}\) and chemiluminescence\(^{199–205}\) detection devices are used for the analysis of seawater samples (see Table 14) demonstrates that FI techniques are suitable for concentrating heavy metals to such a level as to allow the use of less sensitive detectors, without contamination by handling, and in some cases performing reagent purification in the same system.

Selecting the analytical procedure will be then a very demanding task, especially when starting from scratch, that is when one has to decide which equipment to purchase and which determination method to use. The reader is referred to the first paragraphs of this article in order to determine her or his needs.

There is a long-standing competition between analytical spectroscopists and analytical electrochemists about the efficacy of each technique for dealing with traces of metals. We will not enter in this discussion, but most of the literature consulted is devoted to spectroscopies (83%) and thus, unavoidably, there will be some bias towards spectroscopic methods for trace analysis.

With regard to the metal involved, and taking into account the usual concentration level in which the metal is found in seawater or brine, two broad metal groups could be mentioned: those forming some kind of volatile compounds, and the rest.

- **Forming volatile compounds**: As, Se, Te, Pb, Sn, Sb, Ge, Cd and Hg belong to this category. They

may all form some kind of volatile compound, mainly their hydrides (except for Hg, which is volatile as the element). Volatile compounds will be decomposed at high temperatures to yield an atomic cloud, which in turn will yield adequate conditions for atomic spectroscopic methods, free from matrix interferences. For these reasons, HG or cold vapor generation are preferred when analyzing this set of metals, leaving electrochemical methods as a second choice.

**Metals that remain in solution (the rest):** for those metals that do not form volatile compounds easily, a similar criterion for choosing the appropriate technique could be used. Those that will be easily volatilized (not as compounds but as elements) should be analyzed by spectroscopic techniques, as sensitivity will be high if they are easily volatilized. Nevertheless, electrochemical techniques may be preferred for some easily reducible ions or ions which form easily reducible complexes (Co, Cr, Cu, Fe, Pb, Zn).

A new concept has been added to the usual features of merit in analytical procedures: the number of determinations that can be performed per unit time. This is a measure of the capabilities of the technique to deal with a heavy workload, and is used to evaluate its automation potential. Taking into account that most of the sample preparation work might be performed using FI techniques, detection will be the determining step. In this field, multielemental detection devices, such as those that are usually coupled with ICP atom cells, are one of the major improvements in terms of efficiency and operation economy.

Almost all detection devices show instant response to the analyte except for stripping techniques, which require a certain electrodeposition time before reaching the measuring step. Thus, stripping methods may have a poor performance in terms of analysis throughput.

In summary, all techniques presented here will yield the best results when used by trained professionals who have mastered the analytical procedures, and hence the choice of technique will be dictated by common sense rather than for technological reasons.

**ACKNOWLEDGMENTS**

The author wishes especially to thank Dra Mabel Tudino for her wise advice and her collaboration on the manuscript, and to the people of Laboratorio de Análisis de Trazas who have made this work possible.

Hydride Generation Sample Introduction for Spectroscopic Analysis in Environmental Samples

Hisatake Narasaki
Saitama University, Shimo-Okubo, Urawa, Japan

1 Historical Review of Hydride Generation Spectroscopic Analysis

Since AAS was founded by Walsh\(^1\) most metals have been determined rapidly with high sensitivity. However, the sensitivity of metalloid elements such as arsenic (CAS 7440-38-2) and selenium (7782-49-2) were low in AAS, because these elements are difficult to atomize directly. In 1969, Holak\(^2\) generated arsine (7784-42-1) by reaction of zinc (7440-66-6) with hydrochloric acid (10035-10-6) and collected it in a U-tube in liquid nitrogen (7727-37-9). The hydride was then warmed and passed into a flame in an atomic absorption spectrometer. In his method, arsine was separated from solution containing several interferents and determined with high sensitivity. As shown in Equations (1–4) arsenate (15584-04-0) is reduced to arsenite (15502-74-6) and then reduced to arsine, which is decomposed to arsenic (7440-38-2) in the flame.

\[\text{Zn} + 2\text{HCl} \rightarrow \text{ZnCl}_2 + 2\text{H} \] (1)
\[\text{H}_3\text{AsO}_4 + 2\text{H} \rightarrow \text{H}_3\text{AsO}_3 + 3\text{H}_2\text{O} \] (2)
\[\text{H}_3\text{AsO}_3 + 6\text{H} \rightarrow \text{AsH}_3 + 3\text{H}_2\text{O} \] (3)
\[\text{AsH}_3 \rightarrow \text{As} + 3\text{H} \] (4)

Schmidt and Royer\(^3\) reduced the metalloids with SBH (16940-66-2) instead of zinc. By using SBH with acid the reduction yield is increased, the time required is shortened and the reagent blank is lowered. The reaction schemes for arsenic and selenium are shown in Equations (5) and (6). Arsenide is reduced to arsenite and then reduced to arsine, which is decomposed to arsenic thermally.

\[4\text{H}_3\text{AsO}_4 + 3\text{BH}_4^- + \text{H}^+ \rightarrow 4\text{H}_3\text{AsO}_3 + 3\text{H}_2\text{BO}_3 \]
\[ + \text{H}_2\text{O} \] (5)
\[4\text{H}_3\text{AsO}_3 + 3\text{BH}_4^- + 3\text{H}^+ \rightarrow 4\text{AsH}_3 + 3\text{H}_2\text{BO}_3 \]
\[ + 3\text{H}_2\text{O} \] (6)

Selenite (14124-67-5) is reduced to hydrogen selenide (7783-07-5), which is decomposed to selenium, as shown in Equations (7) and (8).

\[4\text{H}_3\text{SeO}_3 + 3\text{BH}_4^- + 3\text{H}^+ \rightarrow 4\text{H}_2\text{Se} + 3\text{H}_2\text{BO}_3 \]
\[ + 3\text{H}_2\text{O} \] (7)
\[\text{H}_2\text{Se} \rightarrow \text{Se} + 2\text{H} \] (8)

Elements that form gaseous hydrides (12184-88-2) at ambient temperature are called generically hydride-forming elements. Table 1 summarizes the properties of hydride-forming elements.\(^4\)

ICP/AES was established between 1964 and 1965 by Greenfield et al. and Wendt and Fassel. Thompson et al. first applied the HG technique to ICP/AES and determined simultaneously arsenic, antimony (7440-36-0), bismuth (7440-69-9), selenium and tellurium (13494-80-9). Houk et al. combined the inductively coupled plasma (ICP) with mass spectrometry (MS) and constructed an ICP mass spectrometer. Powell et al. determined arsenic, selenium, antimony, bismuth, tellurium and mercury (7439-97-6) by ICP/MS using a commercial HG system. There are several review articles on HG spectroscopic analysis. Nakahara reviewed HG/AAS and HG/ICP/AES, and Campbell reviewed HG/AAS and HG/ICP/AES.

2 HYDRIDE GENERATION FOR SPECTROSCOPIC ANALYSIS

2.1 Hydride Generation for Atomic Absorption Spectrometry

2.1.1 Apparatus for Hydride Generation Atomic Absorption Spectrometry

There are several methods to separate the hydrides and to sweep them into a quartz cell in an atomic absorption spectrometer. These include the cold trap method, the batch method and the continuous-flow method. In the cold trap method, the hydrides are trapped in a U-tube in liquid nitrogen and then released thermally into a heated cell in an atomic absorption spectrometer. The cold trap method is used for chemical speciation of the hydride-forming elements, since the sensitivity can be enhanced by enrichment of the hydrides in the cell. In the batch method, the hydrides are purged with carrier gas to the spectrometer as shown in Figure 1.

from solution in the separator and then swept into the cell. Usually nitrogen or argon is used as the carrier gas. The separator and tubes should be replaced with new ones after several uses, since some hydrides such as hydrogen selenide and plumbane are unstable and deteriorate with contaminants. The cell is heated electrically or with a combustible gas. The electric heating controls the cell temperature. The inner wall of the cell should be cleaned with sandpaper or mineral acids after several uses.

A graphite furnace in which the hydrides are trapped and atomized in situ has also become popular.

2.1.2 Detection Limits and Ranges

Table 2 shows the detection limits of the hydride-forming elements using AAS, ICP/AES and ICP/MS. The detection limits with HG are lower than those obtained by solution nebulization in each type of spectrometry and the limits in AAS lie at the parts per billion level. Since the ranges in AAS are regulated by the Lambert–Beer law, the ranges are narrow. Therefore, sample solutions must be concentrated or diluted depending upon the concentration.

2.1.3 Interferences

The HG process is retarded with transition metals such as copper (7440-50-8) and nickel (7440-02-0) and the other coexisting hydride-forming elements. The transition metals are eliminated with Chelex 100 chelating resin for the determination of arsenic, selenium and antimony. Various masking agents are added to complex the transition metals, as shown in Table 3.

2.1.4 Environmental Sample Preparation for Hydride Generation Atomic Absorption Spectrometry

When the total amount of hydride-forming elements is to be determined, the sample should be decomposed. River waters are concentrated with nitric acid (7697-32-2) and sulfuric acid (7664-93-9) including boiling tips. Organic materials are digested with nitric, sulfuric and perchloric acid (7601-90-3). Siliceous residues deposited during the digestion are dissolved with hydrofluoric acid (7664-39-3). Since selenium and antimony are oxidized during the digestion, selenite is reduced to hydride, forming selenite, by boiling with concentrated hydrochloric acid before hydridization (Equation 9).

\[
\text{SeO}_3^{2-} + 2\text{HCl} \rightarrow \text{SeO}_3^{2-} + \text{Cl}_2 + \text{H}_2\text{O} \quad (9)
\]

Antimonate (20175-28-4) is reduced to antimonite with potassium iodide (7681-11-0) solution (Equation 10).

\[
\text{SbO}_4^{3-} + 3\text{I}^- + 2\text{H}^+ \rightarrow \text{SbO}_3^{3-} + \text{I}_3^- + \text{H}_2\text{O} \quad (10)
\]

Lead(II) (14280-50-3) should be oxidized to hydride forming lead(IV) (15158-12-0) with potassium peroxodisulfate (7727-21-1) or potassium dichromate (7778-50-9) just before hydridization.

SBH powder should be weighed out as quickly as possible and away from heat sources, since it is hygroscopic and inflammable. SBH solutions must be stabilized with small amounts of sodium hydroxide (1310-73-2) or potassium hydroxide (1310-58-3) and filtered with a filter paper before use.\(^{25}\) The most commonly used acid in HG is hydrochloric acid, but sulfuric acid is used for the determination of arsenic and tin (7440-31-5).

### 2.1.5 Chemical Speciation by Hydride Generation Atomic Absorption Spectrometry

HG depends upon the oxidation state of the hydride-forming elements and the acidity of a solution containing the elements. Inorganic nonhydride-forming species are determined differentially by subtracting the concentration of the relevant hydride-forming species from the total concentration. Aggett and Aspell\(^{26}\) determined arsenic(III) by HG, maintaining the pH between 4 and 5, and total arsenic by evolution from 5 M hydrochloric acid by AAS. Yamamoto et al. determined antimony(III) at pH 2 and total antimony with 1 M hydrochloric acid.\(^{27}\)

Organic hydride-forming species are difficult to determine by controlling the acidity. As for arsenic, arsenite forms arsine, methylenearsonate forms monomethylarsine [(CH\(_3\))\(_2\)AsH\(_3\)], dimethylarsonate forms dimethylarsine [(CH\(_3\))\(_3\)AsH\(_2\)] and phenylarsonate forms phenylarsine [(C\(_6\)H\(_5\))\(_2\)AsH\(_2\)]. Hydrides trapped in the U-tube are released sequentially on standing at ambient temperature and atomized with an oxyhydrogen flame. The cold trapping methods used for chemical speciation are summarized in Table 4.

Chromatographic methods are the most reliable techniques for the separation of chemical species and are coupled to spectroscopic analyses to enhance the sensitivity, but this article is restricted to methods using HG. The cold trapping method is coupled with gas chromatography (GC) to refine its resolution. Andrae\(^{34}\) speciated arsenite, arsenate, monomethylarsonate and dimethylarsinate by cold trapping GC/AAS after hydridization. HG/GC/AAS is exclusively used for the speciation of organotin compounds.\(^{35}\) Since organotin chlorides are liable to adsorb on the packing materials in GC columns, the chlorides are hydridized with SBH before injection. Effluents from the GC columns are ignited with an oxyhydrogen flame to atomize tin in the effluents. Peaks obtained with capillary columns are better resolved than those obtained with packed columns, but the injection volumes with capillary columns are limited. Samples to be speciated by GC are extracted with organic solvents such as hexane (110-54-3) and purified by cleanup. GC cannot be used to speciate thermally unstable hydrides and nonvolatile species.

High-performance liquid chromatography (HPLC) can be coupled to AAS, ICP/AES and ICP/MS to separate both volatile and nonvolatile species. Samples to be speciated by HPLC are extracted with water-soluble solvents such as methanol (67-56-1) and purified by centrifugation. The effluents from HPLC are decomposed and hydridized with SBH. Table 5 shows some examples of chemical speciation by HPLC coupled with AAS using HG.

There are several review articles on chemical speciation by HG in spectroscopic analysis. Szpunar-Lobinska et al. included the HG technique in their speciation review. Nakahara described chemical speciation by HG spectroscopic analysis and Tao included the HG technique in his ICP/MS speciation review. Ethylation with sodium tetraethylborate is also used for the speciation of metals and organometallics.

2.2 Hydride Generation for Inductively Coupled Plasma Atomic Emission Spectrometry

2.2.1 Apparatus for Hydride Generation Inductively Coupled Plasma Atomic Emission Spectrometry

In ICP/AES, the hydrides are separated from the solution and swept continuously into an argon (8007-14-5) plasma in an ICP atomic emission spectrometer in a similar way to the continuous-flow method in AAS. Since the temperature of the plasma is much higher than that of the quartz cell in AAS, the plasma can be extinguished by ignition of hydrogen (1333-74-0) evolved as a by-product. Hence the instrumental parameters in ICP/AES should be optimized to prevent the plasma from being extinguished. Figure 4 shows a typical HG apparatus for ICP/AES. ICP torches should be cleaned with concentrated nitric acid or aqua regia in a tall beaker after several uses.

2.2.2 Detection Limits and Ranges

The detection limits for ICP/AES range from parts per billion to parts per trillion as shown in Table 2. The dynamic ranges are broad.

2.2.3 Interferences

Interferences in ICP/AES are similar to those in AAS. Therefore, the interferents are treated in a similar manner to those in AAS.

2.2.4 Environmental Sample Preparation for Hydride Generation Inductively Coupled Plasma Atomic Emission Spectrometry

Samples in ICP/AES are treated in a similar way to those in AAS.
2.2.5 Chemical Speciation by Inductively Coupled Plasma Atomic Emission Spectrometry

HPLC is also coupled to ICP/AES. Table 6 shows some examples of HPLC coupled to ICP/AES using HG. Figure 5 shows a schematic diagram of the HPLC system in HG/ICP/AES. Effluents from a high-performance liquid chromatograph are decomposed, hydridized and swept into the torch of an ICP atomic emission spectrometer.

2.3 Hydride Generation for Inductively Coupled Plasma Mass Spectrometry

2.3.1 Apparatus for Hydride Generation Inductively Coupled Plasma Mass Spectrometry

The HG apparatus for ICP/MS is similar to that for ICP/AES. Figure 6 shows a typical hydride introduction system to an ICP mass spectrometer. The ICP torch positions are optimized by sweeping a hydride-forming element not to be determined. The torches should be cleaned in the same way as described for those in ICP/AES. Sampling and skimmer cones are cleaned by warming in 0.1% nitric acid after several uses.

2.3.2 Detection Limits and Ranges

The detection limits for ICP/MS are the lowest and range from parts per trillion to parts per quadrillion, as shown in Table 2. However, the sensitivity is restricted by contamination from the reagent blanks during the preparation of standard and sample solutions. Ultrahigh-purity reagents should be used to minimize the reagent blank.

2.3.3 Interferences

Chemical interferences in ICP/MS are the same as those in AAS and ICP/AES. Hydrochloric acid is usually used to stabilize the hydride-forming elements in dilute standard solutions and to prepare sample solutions. However, the signal of

As has an isobaric interference with $^{40}$Ar$^{35}$Cl, as shown in Table 7. Nitric acid is used instead of hydrochloric acid to avoid the overlap of signals in a quadrupole mass spectrometer. Selenium is determined by measuring the intensity ratio of its isotopes in a quadrupole mass spectrometer, since it has several isotopes and isobaric interferences, as shown in Table 8. The isobaric interference of $^{75}$As with $^{40}$Ar$^{35}$Cl can be resolved in a high-resolution mass spectrometer. Further, the signal of

82Se can be resolved graphically from a 40Ar2H2 broad band in a high-resolution mass spectrometer as shown in Figure 7.50 A silicone-rubber tubular membrane gas–liquid separator has been introduced to avoid signal overlaps as shown in Figure 8.51 The separator removes any vapor of chlorides (16887-00-6) and allows arsenic and selenium of masses 75 and 77 to be separated.

2.3.4 Environmental Sample Preparation for Hydride Generation Inductively Coupled Plasma Mass Spectrometry

The concentrations of acid and SBH solutions used in HG/ICP/MS should be diluted to approximately one tenth of those in HG/ICP/AES. The introduction of large amounts of water vapor and nonvolatile salts into the vacuum system should be avoided. The ion multiplier (detector) of an ICP mass spectrometer deteriorates as a result of the accumulation of salts. Evolution of hydrogen by HG should be minimized to maintain a stable plasma, since combustion of large amounts of hydrogen gas damages the plasma torch by its heat.

2.3.5 Chemical Speciation by Hydride Generation Inductively Coupled Plasma Mass Spectrometry

HPLC is coupled either directly or via hydridization to ICP/MS. The latter technique is very sensitive. Table 9 shows some examples of chemical speciation by HPLC coupled to ICP/MS using HG. Effluents from a high-performance liquid chromatograph are decomposed, hydridized and swept into the torch of an ICP mass spectrometer. Capillary electrophoresis (CE) is combined with ICP/MS owing to its sensitivity. HG/CE/ICP/MS is used for speciation of arsenic with a microporous membrane,53 since the volume of effluents from CE is in the nanoliter range.

In the 1980s, several Program Offices of the United States Environmental Protection Agency (USEPA) investigated the use of immunoassay methods for environmental applications with limited success. Most of the problems were with method ruggedness, i.e. they worked well in clean spiked matrices, but not very well on real world samples. The situation changed significantly in January of 1992, when the Office of Solid Waste (OSW) received its first rugged immunoassay method (for pentachlorophenol (PCP)) that worked on field samples. Several more followed, and through the early and mid-1990s, the USEPA initiated use of immunoassay methodology in its hazardous waste program. The first group of methods incorporated into the OSW’s methods compendium, Test Methods for Evaluating Solid Waste, or SW-846, between 1993 and 1995 were a group of 10 enzyme-linked immunosorbent assay (ELISA)-based screening methods for various environmental analyte classes. These methods were officially ‘approved’ by the USEPA in July, 1997. We provided a great deal of training on these methods to raise the comfort level of the environmental community for their use.

This chapter addresses several major topics including an overview of the USEPA’s major Regulatory Programs; how analytical methods are used in Regulatory Programs; general guidelines for the development of screening methods; specific validation criteria for immunoassay methods; the current status of the USEPA immunoassay method development program; current and potential environmental applications for immunoassay technology; barriers to implementation of immunoassay methods and the steps being taken to overcome them; and future directions and new developments in immunoassay technology for regulatory programs.

The overall future of the technology for environmental monitoring and analysis looks very bright. It offers a cost effective way to generate reliable information upon which to base sound environmental decisions.

1 INTRODUCTION

Immunnoassay technology has several attributes which make it a useful tool for environmental monitoring, e.g. selectivity, sensitivity, portability, and rapid turnaround time. Immunoassay kits can be tailored to target specific analytes or classes of analytes, thus eliminating the need for cleanup methods in most cases to remove interferences. They also have the capability of detecting...
target analytes at very low levels, which are needed in many environmental applications. The portability of immunoassay test kits and speed of analysis allows for rapid analyses to be run on a site in the field. This capability can be especially useful in lowering the costs of cleanup projects because equipment does not have to lay idle while awaiting the results of laboratory analyses.

The USEPA has been looking at the potential use of immunoassay technology for environmental monitoring for several years. The early methods development efforts were unsuccessful because the immunoassay chemistry utilized in the methods was not sufficiently rugged for use on real world environmental matrices. The methods performed well on clean water matrices and spiked samples, but did not perform effectively on natural environmental samples. Because of this poor initial performance on real samples, USEPA Program Office interest in the technology declined.

In January 1992, EnSys, Inc. demonstrated a viable immunoassay test kit for PCB in both soil and water matrices to USEPA’s OSW. Since that time, OSW has been working with several manufacturers to develop and validate a whole battery of immunoassay test kits both for individual analytes and for classes of analytes. The first series of immunoassay methods adopted by OSW for inclusion in its methods manual, Test Methods for Evaluating Solid Waste, (SW-846),\(^{(1)}\) used ELISA as the technique of choice. Currently, OSW has issued more than fifteen immunoassay methods using several different techniques, which can be used for analyses performed under the Resource Conservation and Recovery Act (RCRA).\(^{(2)}\)

### 2 BACKGROUND AND HISTORY

#### 2.1 Overview of United States Environmental Protection Agency Regulatory Programs

##### 2.1.1 Organization

The USEPA is not a single entity. It consists of several regulatory Program Offices which have the responsibility for implementing the major environmental laws passed by the US Congress, as well as several administrative and technical offices which support these regulatory Program Offices. These regulatory Program Offices include the Office of Solid Waste and Emergency Response (OSWER), the Office of Water (OW), the Office of Prevention, Pesticides and Toxic Substances (OPPTS), and the Office of Air and Radiation (OAR).

The various regulatory Program Offices were established at different times in response to Congressional mandates establishing the major environmental laws. These laws are very general in nature, and the USEPA regulatory program offices were formed to set-up the specific regulations needed to administer and enforce these environmental laws. Approaches to regulatory requirements and philosophy vary greatly among the regulatory Program Offices, because of the significant differences in their areas of responsibility. For example, regulations governing air and water, dealing with single media, are necessarily different than those dealing with the management of solid and hazardous waste, which involve a wide variety of media.

##### 2.1.2 Programmatic Regulatory Responsibilities

OSWER is responsible for administering the RCRA through its OSW and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), also known as Superfund, through its Office of Emergency Response and Remediation (OERR). The OW administers the Clean Water Act (CWA) and the Safe Drinking Water Act (SDWA). The OPPTS administers the Toxic Substances Control Act (TSCA) and the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), while the OAR administers the Clean Air Act (CAA). The Office of Administration and Resource Management (OARM) provides administrative support while the Office of Research and Development (ORD), along with several other non-regulatory program offices provide technical support to the regulatory Program Offices.

##### 2.1.3 Regulatory Analytical Methods

The administration of these USEPA regulatory programs involves compliance monitoring, which utilizes a wide variety of analytical methods and techniques. This section of the chapter will focus on the similarities and differences only between the OSWER and OW monitoring programs.

The OSW regulates the management of solid and hazardous waste under RCRA. This includes regulations on generation, storage, and treatment of wastes and waste residuals from active management sites. Most RCRA applications involve site-specific analyses for compliance with permits or other regulations, unlike the general maximum contaminant level (MCL) requirements common to compliance with drinking water regulations. Since RCRA applications encompass a wide variety of media, including, soils, solids, sludges, organic liquids, water, stack emissions, and ambient air, OSW has historically used the performance based measurement system (PBMS) approach to sampling and analysis. This allows for the needed flexibility in matrix-specific and project-specific methods selection for RCRA applications.

The OSW Methods Team publishes a manual of analytical methods applicable for use in the RCRA
Program, Test Methods for Evaluating Solid Waste, SW-846. SW-846 functions primarily as a guidance document. In most cases under RCRA, analyses may be performed using either SW-846 methods or any other method that may be appropriate, since RCRA regulations usually only specify what the analytical requirements are, and not specifically how to do them. Whichever methods are selected, the analyst must demonstrate their applicability for their intended use. This can be done by using a two-tiered demonstration of proficiency: 1) the analyst must demonstrate the ability to perform the method and obtain acceptable results in a ‘clean’ matrix, such as reagent water or Ottawa sand; and 2) the analyst must demonstrate that the method will give acceptable performance in the actual matrix of concern.

However, there are a very few instances in the RCRA regulations where SW-846 analytical methods, in general, must be used to characterize waste. Because of these few cases which require the use of SW-846 methods, all new and revised methods which are included in SW-846 must be published as regulations. OSW is currently working on a regulation under the ‘Reinvention of Government’ guidelines to eliminate this requirement and to publish SW-846 methods as guidance as was the original intent of the manual. Methods which will not become guidance are the ‘method-defined parameters’, or methods which directly define regulatory requirements, e.g. flash point, corrosivity.

The OW, on the other hand, deals with the cleanup of abandoned waste sites under CERCLA (Superfund). Most Superfund analyses are performed using the same multimedia PBMS approach as is used for RCRA. Some Superfund analyses are performed under specific contracts which can use any method deemed appropriate for the application. However, when Superfund methods are written into their contract format, they are very detailed and must be performed as written. Changes or modifications are generally not permitted.

The OERR, on the other hand, deals with the cleanup of abandoned waste sites under CERCLA (Superfund). Most Superfund analyses are performed using the same multimedia PBMS approach as is used for RCRA. Some Superfund analyses are performed under specific contracts which can use any method deemed appropriate for the application. However, when Superfund methods are written into their contract format, they are very detailed and must be performed as written. Changes or modifications are generally not permitted.

The OW, for compliance with both the CWA and SDWA, is required to publish lists of both regulated and unregulated target analytes and to publish approved methods for the analyses of these analytes. Use of alternative methods is not permitted, unless a method equivalency petition is requested by a petitioner and granted by USEPA or other designated authority.

Thus, of the four major USEPA Program Offices for which substantial numbers of analyses are performed, RCRA offers the most flexibility as to choice and application of analytical methods. RCRA only specifies what the analytical requirements are, and leaves the decision as to how the analyses are to be performed to the analyst.

2.2 Developmental History of Immunoassay Methods in United States Environmental Protection Agency Programs

While several USEPA Program Offices investigated the potential applicability of immunoassay methods to their programs, OSW is the first USEPA Program Office to formally incorporate these techniques into its methods program. OSW has taken the Agency lead in developing new immunoassay techniques for its own methods program and is actively working with other USEPA Program Offices to assist them in developing immunoassay methods for their programs.

OSW began evaluation of its first immunoassay method (for PCP) in January 1992, followed by three others in rapid succession. By July 1995, OSW had completed validation of a general overview method and ten individual immunoassay methods (with more than 25 different kits) utilizing ELISA, and published them in the proposed Update III of SW-846. For a USEPA regulatory Program Office, this is very rapid progress. These immunoassay methods covered the analysis of PCP, polychlorinated biphenyls (PCBs), polynuclear aromatic hydrocarbons (PAHs), petroleum hydrocarbons, pesticides and explosives. See Table 1 for a list of these methods. OSW formally approved the first immunoassay method, for PCP, as part of a January 1994, regulation. The rest of the methods in Table 1 were formally approved as part of Update III to SW-846 in June, 1997. All of these methods can be used for any RCRA application for which they can be demonstrated to work.

Between late 1995 and late 1997, the environmental immunoassay industry fell on hard times due to severe cutbacks in remediation projects for which there was a major potential market for use of these environmental immunoassays. This resulted in a consolidation of the

four major manufacturers into a single entity. While the industry was busy sorting itself out during this period, very little was happening in the area of new product and methods development. However, by the end of 1997, several new manufacturers began operating and several new products have either come on the market or are in the final stages of testing, including second generation ELISA kits for PAHs and PCBs, the first immunoassay method (ELISA for mercury) for a metal, immunosensors for explosives, and, finally a series of screening methods for dioxins and coplanar PCBs using a variety of techniques. Some of the other USEPA Program Offices are also looking at immunoassay methods to address some of their analytical requirements. OPPTS is considering using immunoassay methods in its Pesticide Registration Program. OW is beginning to look at using the technology in both the Drinking Water and Wastewater Programs. However, they may have to revise some of their regulations to allow for the use of ‘less than’ values in reporting MCLs or look toward developing quantitative immunoassays.

3 TYPES OF IMMUNOASSAY TECHNOLOGIES EMPLOYED IN ENVIRONMENTAL PROGRAMS

3.1 Enzyme-linked Immunosorbent Assay

ELISA is the most commonly used immunoassay technique for environmental analysis. The immunoassay test products available will often vary in both format and chemistry. The characteristics of a specific product are described in the package insert provided by the manufacturer. This summary is, therefore, general in scope, and is intended to provide a general description of the more common elements of these methods.

Immunoassay test products use an antibody molecule to detect and quantitate a substance in a test sample. These testing products combine the specific binding characteristics of an antibody molecule with a detection chemistry that produces a detectable response used for interpretation. In general, antibody molecules specific for the method’s intended target are provided at a predefined concentration. A reporter (i.e. signal generating) reagent, composed of the target compound conjugated to a signal producing compound or molecule (e.g. enzymes, chromophores, fluorophores, luminescent compounds, etc.), is also provided. The concentration, affinity, and specificity of the products’ antibody influences performance, as does the chemistry of the reporter reagent.

The reporter reagent and antibody molecules of a given product are binding partners, and form a complex in solution. The addition of a positive sample containing the target substance to this solution results in a competitive binding reaction between the target analyte and the reporter reagent for the antibody sites. The antibody concentration, and therefore binding capacity, is limited to prevent the simultaneous binding of both the reporter and target molecules. The concentration of reporter reagent that can bind to the antibody is inversely proportional to the concentration of substance in the test sample.

Immunoassay methods may be heterogeneous (i.e. requiring a wash or separation step), or homogeneous (i.e. not requiring a separation step). In commonly available heterogeneous testing products, the antibody is immobilized to a solid support such as a disposable test tube, and the bound reporter reagent will be retained after removing the unbound contents of the tube by washing. Therefore, a negative sample results in the retention of more reporter molecules than a positive sample. The analysis of a standard containing a known concentration results in the immobilization of a proportional concentration of reporter reagent. A positive sample (i.e. containing a higher concentration than the standard) results in the immobilization of fewer reporter molecules than the standard, and a negative sample (i.e. containing less than the standard) will immobilize more.

A chemistry of the detection of the immobilized reporter is used for interpretation of results. The reporter molecule may be a conjugate of the target molecule and a directly detectable chromophore, fluorophore, or other specie, or conjugated to an enzyme that will act upon a substrate to produce the detectable response. Immunoassay testing products have a quantitative basis, and will produce a signal that is dependent on the concentration of analyte present in the sample. For environmental immunoassay methods, the signal produced is exponentially related to the concentration of the compounds present. Many immunoassay methods use enzymes to develop a chromogenic response, and are termed enzyme immunoassays. Assays that generate a chromogenic response are analyzed photometrically, and use the principles of Beer’s law (absorbance = extinction coefficient x concentration x pathlength) to determine the concentration of analyte in a sample.

Immunoassay methods can provide quantitative data when configured with a series of reference standards that are analyzed and used to construct a standard curve. The signal generated from the analysis of a test sample is used to determine concentration by interpolation from the standard curve. Alternatively, these testing products can be configured to determine if a sample is positive or negative relative to a single standard. Individual immunoassay testing products are reviewed and accepted by the USEPA OSW for the detection of sample analytes in specified matrices. A variety of testing products, produced by several different developers, may
be available for the same compound(s) and matrices. Each of these methods have been formulated using independently developed reagents that may result in significantly different performance characteristics and limitations.

The performance of the immunoassay testing products ultimately relates to the characteristics of the antibody, reporter molecule, and sample processing chemistry. The dose-response characteristics of a method, the position of the standard relative to the claimed action level, and the stated cross-reactivity characteristics of the selected test product, provide relevant information regarding the performance and recognition profile of the selected test product.

The precision, and ultimately the sensitivity of an immunoassay method, is a function of the signal-to-noise characteristics of its dose-response curve, and its operational consistency. Methods having a high slope and low non-specific signal generation produce the most sensitive and precise methods. Signal imprecision applied to a dose-response curve having a shallow slope exhibits proportionally greater imprecision in the calculated concentration than would a method having a steeper slope. In an action level testing product, this would cause the reference standard to be positioned further from the action level, increasing the incidence of false positive results. Similarly, a method having less non-specific signal generation (higher signal-to-noise ratio) will be more sensitive and precise when other characteristics (i.e. dose-response slope) are held constant.

Immunoassay methods are used to detect contamination at a specific concentration below the claimed detection level for the test product. For example, an immunoassay used to detect PCB contamination in soil at 1 ppm will include a standard preparation containing less than 1 ppm. The reference preparation concentration is positioned to minimize the incidence of false negative results at the claimed detection level. For remediation and monitoring applications, where action levels of interest are defined, immunoassay methods should exhibit a negligible incidence of false negative results, and minimal false positives.

For a single point action level test, the concentration of analyte relative to the action level is selected by the developer, and is influenced by the precision (i.e. intra-assay, inter-person, inter-lot, inter-day, etc.), sample matrix interferences and other performance characteristics and limitations of the basic method. The concentration of analyte in the reference materials should be less than, but close to, the claimed action level. The concentration selected for the standard defines the concentration that will produce a 50% incidence of false positive results by the test product. While this issue is one representing limited liability to the operator, it is a practical issue that often requires attention. An immunoassay method for the detection of 1 ppm of PCB using a standard containing 0.8 ppm of PCB will experience a 50% false positive incidence in samples containing 0.8 ppm of PCB, and some incidence of false positive results in a sample containing between 0.8 and 1 ppm. A similar immunoassay that uses a standard containing 0.4 ppm will experience a 50% false positive incidence in samples containing 0.4 ppm of PCB, and some incidence of false positive results in a sample containing between 0.4 and 1 ppm. The closer the standard concentration is to the action level, the better the overall performance.

Cross reactivity characteristics illustrate the specificity of the underlying immunochemistry. The antibody molecules used by a test product bind to a target compound and then participate in the process of generating the signal used for interpretation. Antibody molecules bind by conformational complimentarity. These molecules can be exquisitely specific, and can differentiate subtle differences in the structure of a compound. The binding characteristics of reagents in different test products can vary, and influence the recognition profile and incidence of false results obtained by the method. Immunoassay methods should detect the target analytes claimed by the test product and exhibit limited recognition for compounds and substances not specified.

### 3.2 Reporter Gene on a Human Cell Line

The reporter gene system\(^{(42–50)}\) utilizes a human cell line (101L) into which a plasmid containing a human CYP1A1 promoter and 5'-flanking sequences fused to a reporter gene, firefly luciferase, have been stably integrated. In the presence of CYP1A1-inducing compounds, the enzyme luciferase is produced, and its reaction with luciferin can be detected by measuring relative light units (RLUs) in a luminometer. CYP1A1-inducing environmental contaminants include polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), coplanar PCB congeners, and high molecular weight PAHs.

To quantify the inducing compounds in the sample, the mean response, in RLUs, of the three sample replicates is divided by the mean response of three replicates of a solvent blank, yielding a ‘fold induction’, which is a measure of the increase of the sample response over the background response. Fold induction may be converted to toxic equivalents (TEQ) for PCBs and PCDDs/PCDFs, or benzo[a]pyrene equivalents (B[a]P-Eqgs) for PAHs, based on the fold induction responses to standards containing a mixture of PCDDs/PCDFs, or benzo[a]pyrene, respectively.

This method can be used to estimate the concentrations of PAHs and/or coplanar PCBs in soils over a range from 0.1 to over 100 mg kg\(^{-1}\). In addition, the presence
of PCDDs/PCDFs in the extract will be indicated at concentrations ranging from 100 ng kg\(^{-1}\) to over 1 mg kg\(^{-1}\). These sensitivity estimates are based on the extraction of 40-g solid samples and evaporation of the extract to 1 mL, with the application of 20 µL to one million cells covered by 2 mL of medium. The sensitivity of the method for water samples is approximately 25 times greater, assuming that a 1-L water sample is extracted and the extract is concentrated to the same 1-mL volume (e.g. 4 µg L\(^{-1}\) to 4 mg L\(^{-1}\) for PAHs and PCBs, and 4 ng L\(^{-1}\) to 40 µg L\(^{-1}\) for PCDDs/PCDFs).

The methods contain an optional procedure in which exposures are conducted over two specific time periods (6 and 16 hours). This option allows the test to distinguish between PAHs in the samples and chlorinated compounds, since the PAHs reach maximum induction at 6 hours, while the peak in induction from chlorinated planar compounds (PCBs, PCDDs/PCDFs) is not until 16 hours.

This method is a screening procedure, and depending on project needs. A subset of the samples should be confirmed using quantitative analytical techniques.

### 3.3 Immunosensors

Two types of immunosensor techniques have been evaluated at this time.\(^{(51–68)}\) Both of them for TNT and RDX explosives. The first, a flow cell technique is based on performing a fluorescent displacement immunoassay on a membrane or other solid support in flow. Antibodies immobilized on a solid support (i.e. membrane) are saturated with a fluorescent analog of either TNT or RDX. A test sample is injected into the flow stream. If the appropriate analyte (TNT or RDX) is present in the test sample, it will displace a proportional amount of fluorescent analog. The displaced analog is detected downstream. The fluorescent signal is proportional to the concentration of the analyte in the test sample. This technique can be used as a screening tool to determine if TNT or RDX is present above a critical limit or for quantitation of the explosive in the test sample. To quantitate, the area of the fluorescent peak is compared to standards tested pre and/or post test sample. Results obtained with this method can be used to identify samples with TNT and RDX concentrations between 5 and 200 ppb.

The second, a fiberoptic technique, is based on performing a competitive fluorescent immunoassay on the surface of a fiber optic probe. A fluorescent analog of either TNT or RDX is added to the test sample. The sample is then passed over optical probes which have antibodies immobilized on the surface which are specific for either TNT or RDX. A decrease in maximum fluorescence proportional to the concentration of TNT or RDX in the sample is observed. This technique can be used as a screening tool to determine if TNT or RDX is present above a critical limit or for quantitation of the explosive in the test sample. To quantitate, the percent inhibition is compared to a standard curve.

Results obtained with this method can be used to identify samples with TNT and RDX concentrations between 5 and 200 ppb.

### 3.4 Affinity Chromatography

Affinity chromatography is a potential sample preparation technique whereby the selective nature of immunoassay methods, particularly ELISA, can be used to extract specific compounds or compound classes out of a difficult matrix. The bound analytes can then be desorbed and analyzed by an appropriate chromatographic or other determinative technique, e.g. high-performance liquid chromatography (HPLC).

### 3.5 Dissociation-enhancement Lanthanide Fluoroimmunoassay

The DELFIA (dissociation-enhancement lanthanide fluoroimmunoassay) methodology was developed by scientists at EG&G Wallac, Turku, Finland and the Department of Molecular Endocrinology of Middlesex Hospital, London.\(^{(84)}\) This method is clinically proven and is highly reliable and adaptive. The DELFIA system is based on time-resolved fluorometry of lanthanide compounds such as europium. Lanthanide ions exhibit a unique fluorescence that is characterized by narrowband emission lines, a long decay time, and large Stokes shift. The specific fluorescence of the lanthanide label is measured after a certain time delay following an activation pulse allowing all of the nonspecific background to expire. The DELFIA system and instrumentation allows the detection of four different toxicants in one sample by using four different lanthanide labels each having a distinctive fluorescence spectrum.

### 4 METHOD DEVELOPMENT

#### 4.1 General Guidelines for Development of Screening Methods

The primary applicability that we, in the RCRA Program, see for immunoassay methods is for quantitative screening purposes.\(^{(69)}\) By quantitative screening, we mean setting a quantitative action level (usually the regulatory action level), where a positive response means that the analyte is present at or above the action level, and a negative response tells us that the analyte is either absent or present below the level of regulatory concern. Analyses can be run at multiple action levels giving a useful range of concentrations for specific target analytes.
For example, if we are mapping a site contaminated with PCBs to determine the extent to which it needs to be cleaned up, knowing where PCB levels are <10 ppm, between 10 and 100 ppm, and >100 ppm can be useful in planning and expediting the cleanup.

The OSW Methods Team provides a guidance document (available on-line at http://www.epa.gov/SW-846) to potential developers of screening methods providing guidance on what general validation criteria should be applied to a screening method that will potentially be included in SW-846. While screening procedures need not be fully quantitative, they should measure the presence or absence of target analytes at or below regulatory action levels. Therefore, initial demonstration of method performance involves measuring the percentage of false negatives and false positives generated using the procedure for a single sample matrix. Data should be submitted for split samples analyzed using the developer’s technique and an appropriate SW-846 quantitative method. A candidate procedure should ideally produce no false negatives. Definition of a false negative is a negative response for a sample that contains the stated detection level of the target analyte(s). A candidate procedure should produce no more than 10% false positives. Definition of a false positive is a positive response for a sample that does not contain analytes at the detection level. Between 20 and 50 samples spiked at the detection level should be tested to establish the percentage of false positives. Between 20 and 50 samples spiked at the detection level should also be tested to establish the percentage of false negatives. It is recommended that a sufficient volume of each spiked sample be prepared to complete each test with one lot of material. Sufficient randomly selected aliquots of each spiked matrix should be analyzed by appropriate SW-846 methods to demonstrate sample homogeneity and to characterize the sample in terms of target analytes and potential interferences.

A separate study should also be conducted to establish the effect of non-target interferences. A screening procedure should produce no more than 10% false positives for a set of 20 samples that contains a 100 fold excess of interferences. Positive interferences should be selected that are chemically related to the target analytes and are environmentally relevant. Negative interferences (i.e., masking agents) should also be investigated whenever they are suspected.

Developers should also analyze three different types of samples to provide matrix-specific performance data. These samples should either be characterized reference materials or spiked matrices containing known amounts of target analytes. In either case, bulk samples should be carefully homogenized to reduce sub-sampling errors. The sample matrices should be selected to represent what is regulated under RCRA (e.g., soil, oily waste or wastewaters), not to provide the best performance data. Blanks should be analyzed with each set of samples.

Matrix-specific performance data, including detection limits and dynamic range, are gathered by analyzing ten replicate aliquots of three different sample matrices spiked at two concentrations. If spiked samples are used, suggested spiking levels are the matrix-specific detection limit and 50 times the detection limit. Positive or negative results should be reported for the low concentration samples. Results for high concentration samples should be reported as either semi-quantitative results or as positive/negative with the dilution factor used for the samples. As an alternative to establishing matrix-specific detection limits, specific spiking concentrations are provided for selected target analytes in the guidance document. The low values are normal reporting limits for routine analyses and the high value is 50 times the low concentrations. The Methods Team recognizes that it may not be appropriate to spike all of the target analytes listed within a chemical class.

If the developer has field data, the Methods Team would welcome the opportunity to compare the results obtained using the screening procedure with sample concentrations determined in a laboratory using SW-846 or other appropriate methods.

To summarize, the Methods Team does not require an unreasonable body of data for the initial evaluation of new techniques. Data will need to be submitted on the percentage of false negatives, percentage of false positives, sensitivity to method interferences, and matrix-specific performance data. In addition to these data, the developer should also provide a description of the procedure and a copy of any instructions provided with the test kits.

### 4.2 Validation Criteria for Immunoassay Methods

#### 4.2.1 Screening Methods

In addition to the guidelines for developing screening methods in general, OSW, based on its own experience, has generated some validation criteria specifically applicable to immunoassay methods. These validation criteria, based on the United States Food and Drug Administration (USFDA) 510 K guidelines, are required to be submitted to OSW for review for all immunoassay test kits, whether the kits are to be the basis for a new method or as an alternative kit being added to existing methods. The data needed for validation of immunoassay methods that will be included directly in the method is as follows:

1. cross reactivity with similar analytes;
2. cross reactivity with dissimilar analytes which may be reasonably expected to be found at waste sites;
3. false negative/false positive rates;
4. extraction efficiency (for soil test kits);
5. performance data on spiked samples in environmental matrices validated against standard SW-846 analytical methods;
6. performance data on actual environmental field samples validated against standard SW-846 analytical methods.

Since interferences can be a major problem in environmental analyses, it is important to demonstrate that the analytes of concern can be identified in the presence of similar analytes or dissimilar analytes which may be present in environmental samples. In many instances, substantial cross reactivity with other analytes is a desirable situation. Examples of desirable cross reactivity include sensitivity to esters of 2,4-D as well as the 2,4-D, and for other 3-, 4-, and 5-membered PAHs when testing for phenanthrene in a PAH screening method.

The false negative/false positive rate for a particular immunoassay kit is very important. OSW screening methods are designed to generate 0% false negatives and up to 10% false positives at the regulatory action level. Slightly higher false positive rates are tolerable, e.g. up to 25%. High false positive rates, i.e. >25%, negate the cost effectiveness of the technique because of the excessive numbers of confirmatory tests that would need to be performed. High false negative rates, i.e. >5% at the regulatory action level eliminate the potential use of the method for regulatory purposes.

The extraction efficiency data are important for setting the appropriate action level for a soil analysis. Recoveries are the primary determining factor for making sure that the analyte of concern can be detected at the regulatory action level and for minimizing false negative/false positive rates. Extraction efficiencies need not be quantitative, because of the sensitivity of the antibodies used. However, they must be consistent and reproducible.

The performance data generated from environmental samples spiked with the target analytes give a good indication as to whether or not an immunoassay method will work. However, the performance generated in the field on real environmental samples is the key determining factor on whether or not the immunoassay method is sufficiently rugged to be included in SW-846 as an analytical method.

Additional data that OSW requests, but does not include in the method and treats as confidential business information (CBI), includes dosage curves and the manufacturer’s internal validation and quality control criteria. The slope of the dosage curve can be a good indication of whether or not an immunoassay method will exhibit a high rate of false positives.

Up to this time, all of the immunoassay test kits (>25) that the OSW has evaluated have been extensively tested and validated by the manufacturers. USEPA validation has primarily consisted of confirmation of the manufacturers’ results and performing some additional testing on well-characterized environmental samples, which are more easily available to USEPA regional laboratories.

4.2.2 Quantitative Methods
OSW has issued a guidance document for the validation of quantitative methods, “Guidance for Methods Development and Methods Validation for the RCRA Program”, describing the key elements that need to be met from the Proof of Concept stage through single and multilaboratory validation. The document is also available on the Internet from the OSW Methods Team Homepage at “http://www.epa.gov/SW-846”. Quantitative immunoassay methods would be validated using the same criteria as any other quantitative method.

4.2.3 Revalidation Issues
Based on the successful incorporation of ten immunoassay methods involving more than 25 validated individual test products, the issue has come up as to what type of revalidation of a previously validated method is necessary if that method is changed. Once again, we defer to the USFDA for guidance on this issue. The guidelines that will be included in the revised Immunoassay Screening Methods Development Guidance Document are that for non-substantive changes, i.e. changes that do not affect the basic chemistry of the method, no revalidation will be necessary. An example of this type of change would be change of an inert washing solution in an ELISA kit.

If the manufacturer decided to change the format of the product, e.g. from a tube reaction to a home pregnancy test kit type format without changing the chemistry, the manufacturer would need to do a partial revalidation. This partial revalidation would need to be sufficient to demonstrate that the format change has not adversely affected or changed the chemistry and that the new kit gives the same results as the old one on split samples.

If the manufacturer changes the chemistry in an existing product, this would be considered as a new product and would require a new validation.

5 STATUS OF THE UNITED STATES ENVIRONMENTAL PROTECTION AGENCY IMMUNOASSAY METHODS DEVELOPMENT PROGRAM
5.1 Current Validated Methods
The first eleven immunoassay methods (see Table 1) were formally approved for incorporation into SW-846
by regulation in June, 1997. The generic Immunoassay method (Method 4000) and the ten individual ELISA methods may be used for any analytical application for which they can be demonstrated to be appropriate. No regulatory barriers remain to prevent the use of these methods.

The five new methods included in Table 2 have been formally validated and accepted by OSW’s Technical Workgroup. However, until the regulations removing the requirements to adopt new methods through regulatory action are removed (expected to be completed by the end of 2000), the use of these methods may be limited by some regulatory restrictions. However, for most of the applications for which they are intended to be used, there are no actual regulatory barriers, only perceptions.

Method 4425, developed by Columbia Analytical Services (CAS), is a gross screening method using a reporter gene on a human liver cell line to screen for PAHs, PCBs and dioxins. The method can distinguish between PAHs and chlorinated compounds by differences in reaction time. The method can give useful semiquantitative information only on well characterized sites in the monitoring mode.

Method 4500, developed by BioNebraska, is the first USEPA immunoassay method for a metal, mercury. It provides semiquantitative screening data for mercury extracted from soils with acid and followed by a colorimetric determination using ELISA.

Methods 4655 and 4656 are immunoassay probe methods for TNT and RDX explosives developed by the Naval Research Laboratory (NRL) using previously developed ELISA antibodies used in the earlier test kit methods (see Methods 4050 and 4051 in Table 1) and detection using a flow cell technique based on performing a fluorescent displacement immunoassay on a membrane or other solid support in flow or a fiber optic technique based on performing a competitive fluorescent immunoassay on the surface of a fiber optic probe.

Method 4670 developed by Ohmicron (SDI, Inc.) is a competitive ELISA immunoassay method for the quantitative determination of triazine herbicides as atrazine in drinking water. This method will be discussed in more detail in section 6.5.

Copies of the methods in Table 2 are available now or will be shortly on the OSW Methods Team Homepage at “http://www.epa.gov/SW-846”.

5.2 Methods under Development

The six methods listed in Table 3 are in various stages of development. Methods 4025 for dioxin and 4026 for coplanar PCBs are ELISA methods from Cape Technologies and should have their validations completed by the end of 1999. The validation of the DELFIA method for dioxin TEQ, Method 4430, from Hybrizyme should also be completed around the same time. The other three methods, Method 36xx for affinity chromatography, Method 4016 for 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and Method 4060 for TCE are all only in the beginning stages of development at this time.

Dioxin is a general term that describes a group of highly toxic chemicals that are extremely persistent in the environment. These compounds have been of major interest to immunoassay method developers. There are 210 different dioxin and furan congeners, 17 of which have been determined to be toxic. Each toxic congener has been assigned a toxic equivalency factor (TEF) which expresses how biologically active it is as compared to 2,3,7,8-tetrachlorodibenzop-dioxin (TCDD), the most toxic congener. Studies have demonstrated that the toxicity of the individual congeners is additive. The additive effects of these compounds are expressed as total TEQ in comparison to TCDD.

The scientific community has now identified a common pathway responsible for most, if not all, of the harmful effects associated with exposure to dioxin and related compounds. The interaction of dioxin-like compounds with a cellular protein known as the “Aryl hydrocarbon receptor” or “Ah receptor” represents the first step in a series of events that ultimately alters normal physiological processes. Exposure to dioxin-like molecules has been

TCE, trichloroethylene.
linked to a variety of illnesses including cancer, harmful reproductive and developmental effects, immunotoxicity, diabetes, and endometriosis.\(^{388}\)

Discovery of the Ah receptor provided a key to understanding the molecular mechanism of dioxin toxicity. The Ah receptor resembles the broad category of steroid hormone receptors and like those receptors, it regulates gene transcription. The receptor is capable of a high degree of structural discrimination between molecules and of transducing signals at very low concentrations. The toxicity of the 17 dioxins and furans results from changes in the expression of critical genes following binding and activation of the Ah receptor. Therefore, biological systems respond to the cumulative exposure of Ah receptor-mediated chemicals rather than to the exposure to any single dioxin-like compound, thus providing the molecular basis for the empirically derived TEF and TEQ value system.\(^{89}\)

Several different approaches have been used for screening of toxic dioxins and furans by immunoassay. These include the reporter gene approach (Method 4425) described in the previous section, ELISA (Method 4025) and DELFIA (Method 4430).

Cape Technologies’ Method 4025 (ELISA) is a screening method that measures TEQ of dioxins and furans in soil and water extracts. It does involve a detailed sample preparation procedure, unlike the test kits for simpler target analytes. Therefore it is more suitable for laboratory use than for field use. The method is readily sensitive to 500 ppt TEQ in soils.\(^{90}\)

Hybrizyme’s dioxin assay (Method 4430) is based upon a recombinant version of the Ah receptor gene which is used in the assay to accurately measure dioxin-like compounds. The DNA sequence adjacent to the Ah receptor gene has been modified so that the recombinant protein can be manufactured in large quantities and easily incorporated into an immunoassay format. Accordingly, the assay embodies ‘nature’s perfect device’ for detecting the presence of these compounds and provides the user with a ‘risk-based’ approach to TEQ analysis. In conjunction with the Ah receptor-based assay system, Hybrizyme has developed sample processing procedures that will allow the test to selectively detect dioxins and furans, co-planar PCBs, or carcinogenic PAHs such as benzo[α]pyrene.

The Method 4430 dioxin assay is noncompetitive by design. Almost all immunoassays that detect small molecules are competitive in nature. The sensitivity of noncompetitive assays increases with lower

APAH, anthracene polynuclear aromatic hydrocarbons; CPAH, carcinogenic polynuclear aromatic hydrocarbons; SCHC, short-chain hydrocarbons.
immunoreactant concentrations since, at low concentrations, a variation in the number of competing molecules has a larger impact on the interaction with the labeled species. However, according to the law of mass action, the low antigen and antibody concentrations considerably reduce the rate of complex formation and, at very low concentrations, the accuracy tends to be poor. As a non-competitive assay, the Ah receptor test will utilize a large excess of receptor to obtain a maximum signal for the compound being tested. Even at very low concentrations of molecules, a high fraction will react if the receptor is added in excess. Although not practically achievable, the theoretical limit of the detection for this system is one molecule.\(^{(91)}\)

The Hybrizyme DELFIA assay provides an ultra-sensitive measurement system for detecting dioxin-like molecules that interact with the Ah receptor. By utilizing molecular cloning methods and clinical instrumentation, the method provides the analytical laboratory with a product containing built-in QA/QC routines, retained standard curves, LIMS compatible data-reduction, and the ease-of-use demanded in state-of-the-art clinical laboratories.

Cape Technologies has also developed an ELISA-based immunoassay for coplanar PCBs (Method 4026)\(^{(93)}\) similar to its dioxin immunoassay (Method 4025). The method is sensitive to the 14 dioxin-like PCB congeners and is in the process of field testing to complete the final validation for inclusion in SW-846.

### 5.3 List of Validated Immunoassay Test Products

Table 4 provides a list of individual immunoassay test products that have been validated by OSW and were commercially available. Due to the merger of the four major manufacturers in 1997 and a reorganization of product lines, some of the listed ELISA kits may have been discontinued.

### 6 ENVIRONMENTAL APPLICATIONS

#### 6.1 Advantages and Disadvantages of Immunoassay Methods

The use of immunoassay methods provides many advantages to the analyst in solving environmental problems. Some of the significant advantages derived from using this technology include selectivity, sensitivity, portability, rapid turnaround time, improved data quality, and overall cost effectiveness. Immunoassay methods by their very nature and design are very selective in their scope of applicability, i.e. they are designed to be very specific for the analysis of either an individual compound, e.g. 2,4-D or toxaphene, or an individual class of compounds, e.g. PAHs or PCBs. Compounds other than the target analytes which may be present on a potential site do not react under the conditions and reagents used for the particular methods.

Sensitivity is another advantage of immunoassay technology. Many target analytes can be detected in the ppm range or low ppb range, if necessary. Many commercial products can be obtained or prepared to operate in several ranges, e.g. 1, 10 and 100 ppm, allowing for useful site mapping to determine which areas of a contaminated site are in need of cleanup and which are not. Some kits can operate both at the low ppb range and with appropriate dilution in the ppm range. An example is the 2,4-D kit (Method 4015) developed by Ohmicron which was designed to be sensitive to drinking water MCLs of 18 ppb, and could also be used with appropriate dilution for RCRA toxicity characteristic (TC) analysis at a 10-ppm regulatory limit.

Portability is another advantage of immunoassay technology. Most immunoassay products are sold in kit form and utilize very small apparatus, both for sample handling and in the colorimeter used for detection. Thus, it is very easy to take these kits directly to a field site for use or to an on-site mobile laboratory. However, when working directly on a field site with immunoassay methods, the operator must be very careful to follow the manufacturer’s instructions on the package insert as to operating parameters, particularly with respect to effective temperature range. If the method is performed outside of the manufacturer’s specified temperature range, i.e. if performed at 10°C when the specified range is 15°C to 30°C, the method will not work and will give erroneous data. Most kits that are operated outside of their designated temperature range are usually designed to give positive results, i.e. potential false positives.

Rapid turnaround time is another advantage of immunoassay technology. Most samples can be run in less than an hour directly on-site. This is particularly useful in a remediation activity where soil is being removed and the site manager needs to know when the cleanup level has been achieved. At this point the excavation can be demonstrated to have been completed. This can result in a considerable cost savings over the conventional approach of sending a few samples out to a laboratory and waiting several days for the analytical results to come back. By this time, a great deal of unnecessary expenditure for excavation or equipment demurrage may have occurred.

Use of immunoassay technology can also improve the overall data quality of a remediation project. The rapid turnaround time and significantly lower cost per sample over conventional laboratory methods, e.g. gas chromatography/mass spectrometry (GC/MS) or gas chromatography/electron capture detection (GC/ECD),
can result in the ability to run a much larger number of samples during the remediation project. The data from these additional samples provide a much better characterization of the site and the progress of the remediation than would the data from the relatively few conventional samples that may normally be analyzed.

The use of immunoassay technology can be very cost effective compared to conventional technologies for all of the reasons previously mentioned in this section. However, since immunoassay methods are used primarily as quantitative screening methods, one still needs to do appropriate confirmation analysis using conventional analytical methods to support the immunoassay data. OSW recommends that approximately 5 to 10% of the immunoassay samples that generate negative results be confirmed by conventional laboratory techniques, depending on the number of total samples that are run for the particular project. Confirmation of positive samples may be done on a routine basis or as needed.

However, despite the many advantages of using immunoassay methods, there are a few disadvantages as well. The primary disadvantage is that, because they are very selective in nature, they are not effective tools for characterization of an unknown site. The most effective use of immunoassay methods is in the monitoring mode for a well-characterized site, rather than in the survey mode when one is trying to determine what compounds are the primary contaminants of the site.

Another disadvantage is that for class-specific methods, the immunoassay kit does not differentiate between the individual analytes present. Also depending on the nature of the antibody employed, the specific method may not be sensitive to all compounds within that particular class. Some of the early PAH kits (Method 4035) who had antibodies designed on phenanthrene were not particularly sensitive to PAHs containing more than four rings. An additional kit sensitive to benzo[a]pyrene was needed to analyze for PAHs containing 5 to 7 rings. A second generation kit with an antibody targeted to a four-membered ring (chrysene) now covers the entire range. In addition, some of the early PCB kits (Method 4020) were designed around the congeners present in Aroclor 1248 or Aroclor 1254 and did not respond well to the less chlorinated congeners found in Aroclor 1242. Thus, it is important to have a good site characterization prior to employing immunoassay methods in the monitoring mode.

Another factor of which an operator needs to be aware is the type of potential matrix interferences that may be present on a site to prevent an immunoassay method from performing. Five per cent of an oil could prevent most soil PCB kits from working, except for the one product that was specifically designed to perform in an oily matrix. Moisture levels and pH can also prevent some kits from performing as expected by the user or claimed by the manufacturer. The precautions necessary to overcome these problems are usually included on the package inserts from the manufacturers.

A peripheral issue is the extent of training necessary for an operator to become proficient in the use of the immunoassay kits. Early on, the sales push was that a minimally trained operator could take a kit, maybe read the instructions, and then go out into the field and start performing analyses. In reality, this was not the case at all. Operators need to be trained well in the nuances of handling immunoassay kits. A non-scientist, in particular, needs to be educated very intensely as to which steps in the procedure are critical and must not be changed. In the validation studies for the first 10 ELISA methods, OSW found that analytical chemists, by far, obtained the best analytical results.

### 6.2 Implementation Issues

There have been some initial barriers to getting immunoassay methods accepted for routine use in the environmental community. These barriers have been both technical and cultural in nature. The technical barriers include lack of knowledge about analytical options; use of expensive time-consuming methodology when more efficient methodology is available; poor planning of the initial analytical scheme; failure to identify proper questions to be answered which can result in generation of data inappropriate to address the problem at hand. Cultural barriers include inappropriate or excessive regulatory restrictions on use of new methods, e.g. requiring the use of only promulgated methods for program applications that do not have these requirements, and requiring the use of expensive broad-scope methods, e.g. GC/MS, for limited monitoring applications for only a few known and well-characterized analytes.

An additional issue of concern was whether the Regulatory Program Offices could live with analytical values that were not a specified number, i.e. a less than value (usually the regulatory action level) vs. a definite number (0.1 ppm) or a range of values (>5 and <50). We, in the RCRA Program, decided that we could indeed use these values to answer the basic questions for which these analyses were performed, i.e. Have we attained our cleanup criteria? Where do we have to focus our cleanup efforts? We decided that our normal operating procedures for confirming quantitative screening results would be to use the standard reference method to confirm positives and to spot check a certain percentage (usually 10%) of negative results.

Other Program Offices in USEPA, such as the OW may have some restrictions in their current regulations which require them to generate a definite analytical value. The
Office of Groundwater and Drinking Water (OGWDW) has decided to include quantitative immunoassay screening methods in their regulations, the first of which will be Method 4670 for triazines as atrazine. This potential application is described in section 6.5.

OSW has initiated a major effort to educate USEPA permit writers, enforcement people, and others who deal with analytical methods in their jobs as to what the regulatory aspects of using RCRA methods really are. Many of these people were not aware that RCRA regulations did not require the use of only promulgated methods for most applications. The Methods Team has developed a formal training program for RCRA personnel in the Regions and at Headquarters to make them aware of what methods the regulations really allow them to use for RCRA applications, and how to plan an efficient, cost effective sampling and analysis plan.

State programs are a little more difficult. Since RCRA is a Federal Program which has been passed down to most States to administer, the State regulations can be more restrictive and tend to vary greatly. Some States mandate the use of SW-846 methods for all RCRA analytical applications within the State. Flexibility within State Programs varies from allowing only the use of promulgated methods to using any method that may be appropriate for an application. Through dialogue with the USEPA Regions and Headquarters, some of the States are beginning to take an interest in utilizing immunoassay methods. TPHs analysis is the major focus right now in State Programs, since it is not regulated at the Federal level. Several States are beginning to adopt Method 4030 for use in their Underground Storage Tank (UST) Programs, e.g. Georgia and California.

### 6.3 Examples of Performance Based Measurement Systems

The USEPA has established a policy that, where possible, the Agency will use the PBMSs approach in its monitoring programs for generating environmental data. The Agency defines PBMS as a set of processes wherein the data quality needs, mandates or limitations of a program or project are specified, and serve as criteria for selecting appropriate methods to meet those needs in a cost-effective manner. The PBMS approach has been the basis of the RCRA monitoring program since its inception back in 1980. The inherent flexibility of this approach is an absolute necessity for a program that has responsibility for overseeing analyses in a wide variety of diverse media. The approach is very simple in nature. Rather than focusing on a prescriptive method approach, where following a published method exactly as written is the main requirement, the PBMS approach focuses on a series of questions to be answered about a specific application. These questions are based on the scientific method and focus on whether a selected method or methods can provide performance appropriate to address the data quality requirements of a particular project. The questions include:

1. **What is the purpose of this analysis? (Why are we doing this analysis?)**
2. **How (for what action) are the data generated from this analysis to be used?**
3. **What are the data quality needs for this project, i.e. how good does the data have to be for it to be useful for its intended purpose? (Including regulatory drivers, target analytes, matrices, concentration levels, statistical confidence levels, etc.)**

Immuoassay methods are the ultimate tools for demonstrating and using this PBMSs approach. They are designed and manufactured around specific performance criteria, i.e. methods appropriate for use in Method 4020 are capable of determining whether a soil sample contains PCBs above a concentration of 5 ppm to a 95% upper confidence limit around the mean. There are currently four validated immunoassay products in Method 4020 that can meet these stated manufacturers’ performance criteria, all of which utilize different chemistries.

### 6.4 Applications as Screening Methods

#### 6.4.1 In the Field

OSW decided to take a cautious approach to the introduction of a new technology to the environmental field, with which most analytical practitioners were unfamiliar, and limit the initial applications of immunoassay methods to quantitative screening. We were aware that the technique had been used in Clinical Laboratories for many years in both screening and determinative applications. Since Regulatory Agencies tend to be slow to accept new and different approaches to analysis, anyway, we decided to take a “walk before you run” approach to introducing the new methodology to the people actually doing site assessments and cleanups.

The two primary applications of immunoassay methods in the RCRA Program are mapping of contamination at well-characterized sites slated for cleanup and monitoring the effectiveness of the cleanup activities. Immunoassay lends itself very well to these two particular applications. It is not particularly applicable to the identification and characterization of unknown contaminants at waste sites when compared to much more comprehensive techniques such as GC/MS. However, the reporter gene method (Method 4425) for planar aromatic compounds can be
used to determine the presence of and approximate concentrations of PAHs and chlorinated planar organics and distinguish between them. For monitoring applications of known contaminants, the specificity, sensitivity, and cost effectiveness of quantitative screening immunoassay methods are excellent.

Over the past few years, the general acceptability and willingness to use immunoassay methods within the USEPA Regions for RCRA and Superfund applications has increased exponentially. A significant factor in this change of attitude, in addition to OSW’s attempts to educate users in the applicability of the technique, is the specter of shrinking budgets. Field people who are charged with actually doing cleanups are looking for more cost effective ways to do their jobs with less available money. A technique, such as immunoassay methodology, which can generate results of known quality in real-time, and can keep the bulldozers rolling can contribute significantly to reducing the costs of cleanups, and is being looked upon more favorably.

The initial application of immunoassay technology in the RCRA Program was for determining compliance at wood surface treating facilities with PCP regulatory limits. The selectivity and sensitivity of the immunoassay method easily met the regulatory action limit of 0.1 ppm. Use of the PCP immunoassay method (Method 4010) for compliance monitoring was encouraged by OSW and the method was added to SW-846 as a part of the Wood Surface Treatment Rule in 1994.

The major applications for which immunoassay methods are currently used in the RCRA Program are site mapping and monitoring cleanups at sites contaminated with PCBs. Use of the PCB method (Method 4020) has resulted in cost savings at many sites in several Regions. The speed and low cost of the test allows for more extensive mapping of contamination at a site, because many more samples can be analyzed on-site, thus generating a more detailed map of the site. This results in lower cleanup costs, since the cleanup efforts can be directed only at the places that need to be cleaned up, instead of to a broader area. The design of the method allows for rapid determination of whether or not the site cleanup level has been met, thus reducing costs of cleanup in both time and equipment. With the availability of the PAH method (Method 4035) and several types of kits with various sensitivities, the technique is now beginning to be used to monitor sites contaminated with PAHs.

Another major application within OSWER is for mapping and cleanup of sites contaminated with petroleum hydrocarbons from leaking storage tanks partially for the States. The TPH method (Method 4030) is effective for determining gasoline, diesel, kerosene, and jet fuel at most State-required cleanup levels.

The recent Department of Defense cutbacks set into motion a large number of military base closures in the United States, resulting in a plethora of site cleanup projects. The primary analytes of concern for these base closure cleanups were explosives, petroleum hydrocarbons and PCBs, all of which could be monitored using immunoassays and other screening techniques. The immunoassay ELISA methods for TNT (Method 4050) and RDX (Method 4051) have been used extensively along with the immunosensor methods (Methods 4655 and 4656) and the colorimetric screening Methods 8010 (for RDX) and 8015 (for TNT).

The ELISA method for mercury (Method 4500) has been used effectively to monitor the progress of the soil cleanups of several Superfund sites contaminated with mercury.

6.4.2 In the Laboratory

Immunoassay methods have been used in many laboratories to screen samples for high levels of contaminants to prevent instrument downtime. The dioxin screening method (Method 4025) was primarily designed for use in a laboratory, rather than in the field, because of the detailed sample preparation procedures involved. An effective dioxin screening method can result in significant cost savings for monitoring dioxin-contaminated sites. A negative immunoassay screening result can eliminate the need for a high resolution GC/MS analysis costing between $1500 and $2000 each. The method has been validated on a set of 56 real world soil samples and gave results that were 91% correct with 9% false positives. No false negatives were reported. It has also been used to screen river sediment samples and food samples potentially contaminated with dioxin.

6.5 Applications as Quantitative Methods

At the time of writing, there are very few quantitative applications for immunoassay methods. There are a few being developed. USEPA’s Drinking Water Program is planning to incorporate Method 4670 for triazines as atrazine into its screening regulations. Current regulations require that drinking water suppliers test their supplies quarterly for atrazine at an MCL of 3 ppb. Method 4670 is appropriate for this measurement requirement, because it can measure these compounds sufficiently below the 3 ppb MCL to be effective. Since it also has a positive crossreactivity to other triazines, e.g. simazine and the like, the data generated as atrazine would be an overestimation and thus would be a conservative measurement.

Some of the more selective screening methods, e.g. TNT, RDX, and 2,4-D were originally submitted as screening methods for reasons described previously.
However, they are sufficiently selective to allow their use as quantitative methods. The TNT methods have been used for some quantitative applications on military base cleanups. They tend to generate high results with respect to TNT, because they also exhibit significant (and desirable) cross-reactivity to TNT breakdown products such as DNT and DNB.

7 FUTURE DIRECTIONS

The environmental immunoassay method program has come a very long way, from nonexistent in early 1992 to a significant and viable program with a variety of available methods utilizing several different immunoassay technologies today. However, we still intend to continue to push ahead and keep the new methods coming and remain current with the state-of-the-art.

The primary focus right now is on completing the validations of the dioxins and coplanar PCB methods in Table 3, which is expected to be done by early 2000. We are also interested in continuing with the development of additional quantitative immunoassay methods for specific target analytes. We are continuing to investigate the applicability of immunoassay in the area of affinity chromatography.

Another area of interest for continued development is that of immunosensors. Several Federal Agencies are interested in further developing this technology beyond the realm of explosives. We are in the process of planning some preliminary projects, beginning in 2000, to complete the development of new immunosensors for PAHs, PCBs, and TCE.

Now that the industry has sorted itself out after the mergers of 1997, there are a number of small, energetic companies with a broad base of expertise in a wide variety of immunoassay techniques. We, in OSW, plan on continuing our productive relationship with these industrial partners to bring the best of immunoassay technology to bear on future environmental problems.

ACKNOWLEDGMENTS

The author would like to acknowledge Gail Hansen of the OSW Methods Team for her help in proofreading the manuscript and to several contributors of technical documents that helped him a great deal by providing him with the information that he needed to finish certain sections of this chapter. These contributors include Bob Harrison of Cape Technologies, Randy Allen of Hybrizyme, Jack Anderson of Columbia Analytical Services, and the other developers of immunoassay methods with whom I have worked over the years, particularly Steve Friedman of Sylvanus Laboratories, who has been my primary mentor in immunoassay technology over the years.

1 INTRODUCTION

In recent years, there has been ever increasing concern about the concentration levels of various trace and ultra-trace elements in environmental samples. In spite of this growing interest, the efforts of most environmental scientists appeared to be centered around limited numbers of typical pollutants. Phenomena occurring in the “real world” are for the most part so complicated that usually no clear cut conclusions can be reached when research work is limited only to the element in question. But because elements within the same Group and/or sub-Group of the periodic table possess similar chemical as well as physical properties, it can be expected that more comprehensive understanding will be obtained when all the elements are studied comparatively in relation to their position in the periodic table. In addition to this, various kinds of elements, which were not commonly used in the past, are now increasingly consumed by modern industries in the production of numerous new materials. There is a strong possibility that these industrial products will be disposed of in the environment and, hence will cause new types of environmental pollution. In order to cope with this situation, it seems essential to employ analytical techniques that possess rapid simultaneous multielement capabilities like ICPMS.

2 HISTORY

ICPMS is a relatively new technique that combines two well-established analytical tools (inductively coupled plasma (ICP) and mass spectrometry (MS)) to produce an instrument with powerful potential in the field of multielement trace analysis. ICP is used as a source of ions rather than as a source for optical emission measurement (as in inductively coupled plasma atomic emission spectrometry, ICPAES). Since the introduction of the first commercial ICPMS instruments in 1983, the technique has gained increasing attention from analytical chemists. And the total number of instruments installed worldwide by the end of 1998 was estimated to be about 3000.

The major advantages of ICPMS over other analytical methods are:

1. increased sensitivity and wide dynamic range
2. high selectivity
3. rapid multielement capability
4. simplicity in the spectra
5. low and uniform background
6. the ability to measure specific isotopes.

It should be noted, however, that there are also several disadvantages. These are as follows:

1. lower precision compared with ICPAES and atomic absorption spectrometry (AAS)
2. the total dissolved salts should be less than 1000 ppm
3. severe matrix effects
4. higher cost of the instrument.

3 INSTRUMENTATION

3.1 Instrument Overview

A schematic representation of the main components of a typical ICPMS instrument is shown in Figure 2. Although ICPs are basically similar to those that have been used in emission spectrometry (ICPAES) for many years, the torch is mounted horizontally rather than vertically (torches have also been mounted horizontally in ICPAES). The interface between the plasma and the mass spectrometer consists of two cones: the first is called the sampling cone and the other one that is installed behind the sampling cone is known as the skimmer cone.

Transfer from the skimmer to the mass analyzer is effected by a system of electrostatic lenses, which extract the positively charged ions and focus the ion beam in a form suitable for transmission through the quadrupole mass filter. The mass filter transmits the ions of a particular selected mass to charge ratio \((m/z)\) to an ion detector (channel electron multiplier) that registers the ions. Each naturally occurring element has a unique and simple pattern of near-integer mass to charge ratio corresponding to its stable isotopes. Accordingly, the identification of an element is very simple and straightforward. The number of registered ions from a given isotope depends, of course, on the concentration of the relevant elements in the sample. More detailed descriptions of the instrumentation of ICPMS have been presented elsewhere.\(^{3–5}\)

3.2 Inductively Coupled Plasma

The ICP is produced by passing ionized Ar gas “seeded” with a few electrons from a Tesla Coil through a quartz torch located inside a Cu coil that is connected to a radiofrequency (RF) generator. The high-frequency currents from the generator flow in the Cu coil and thus generate oscillating electromagnetic fields. Electrons and ions passing through the oscillating electromagnetic field flow at high-acceleration rates in a closed annular path inside the quartz tube. The direction and strength of the induced magnetic fields varies with time, resulting in electron acceleration at each half cycle. Collisions between accelerated electrons (and ions) and unionized Ar gas cause further ionization. However, other Ar atoms impede the movement of this current of charged particles and cause ohmic heating of the gas.

3.3 Sample Introduction Systems

A key advantage of ICPMS over other types of MS is that the ion source (ICP) is located outside the vacuum system and allows much simpler sample introduction.
For analysis by the ICPMS technique, samples must be in a form which can be carried in a stream of Ar gas (nebulizer gas). The most convenient method for sample introduction into the gas stream is the generation of a fine aerosol using a nebulizer and a spray chamber, as illustrated in Figure 2, because most of analyses are carried out on liquid samples.

3.3.1 Pneumatic Nebulization

The basic principle of pneumatic nebulization is that the stream of sample solution is disrupted by a high velocity gas flow to produce a spray of droplets. The construction of a pneumatic nebulizer suitable for ICPMS demands much greater skill because of the low gas flow rates. A spray chamber is attached to the nebulizer to remove most of larger droplets and to ensure that only the smallest solution droplets (less than 10-µm diameter) are carried into the plasma to avoid excessive cooling of the plasma. There are essentially three types of pneumatic nebulizer commercially available for ICPMS: concentric flow, crossflow, and Babington-type nebulizers. For those interested in more detailed information on this subject, reviews by Sharp\(^{(6,7)}\) can be recommended.

The most widely used nebulizer is the Meinhard concentric glass nebulizer,\(^{(8)}\) shown in Figure 3. This all-glass device is constructed by standard glassblowing techniques. Nebulizer gas (Ar) at a flow rate of around 1 L min\(^{-1}\) is passed through the outer glass tube. The pressure drop generated (Venturi effect) causes the sample solution to be drawn up into the axial capillary and simultaneously discharged into aerosol droplets. The fragility and fineness of the sample inlet capillary and of the annular gas orifice are major drawbacks of this type of nebulizer. Blockage caused by the accumulation of salt particles (salting-up) and/or suspended solids is common, although a high salt tolerant type is also available.

The operation of the crossflow nebulizer is based on the well-known “scent-spray” principle.\(^{(9)}\) A horizontal jet of gas passes across the top of a vertical tube. The reduced pressure so generated sucks the sample solution up the vertical tube, and at the top is dispersed into fine droplets (Figure 4). Although the analytical performance offered by the crossflow nebulizer is similar to the concentric type, it can be constructed from various materials other than glass. It is possible, therefore, to introduce solutions containing high concentrations of HF.

In the Babington-type nebulizer (Figure 5), the sample solution flows freely over an open slot or V-groove.\(^{(10,11)}\) Gas forced through a small aperture in the bottom of the groove ruptures the fed solution to produce an aerosol. As the solution is simply flowing over a slot, rather than passing through a fine capillary, this type of nebulizer shows high tolerance towards samples with large amounts of dissolved solid, and even to slurries.\(^{(12,13)}\)

3.3.2 Ultrasonic Nebulization

The pneumatic nebulizer has been commonly used for sample introduction into the ICP. However, transport efficiency is extremely low, owing to the very wide range of droplet sizes produced. Ultrasonic nebulization greatly increases the transport efficiency and hence results in better analytical sensitivity and/or detection limits.\(^{(14-16)}\)

A schematic diagram of the ultrasonic nebulizer (USN) used in the author’s laboratory is shown in Figure 6. A peristaltic pump is used to deliver the sample solution to the oscillating surface of the quartz plate. Aerosols with smaller and more uniform particle sizes are produced and transported first to the heated tube, and then to the condenser by the nebulizer Ar gas. Most of the water in the aerosol is removed by this process and only the dry aerosol is introduced into the plasma. The temperature of the heated tube is around 120°C (slightly higher than the boiling point of water) and that of the condenser is usually set around 1°C (near freezing point), and the sample introduction rate is typically 2–4 mL min\(^{-1}\). CETAC Technologies has introduced a membrane desolvator to couple with the USN. The aim was to preserve the high
efficiency of USN and significantly reduce solvent loading into ICP.

### 3.3.3 Direct Injection Nebulizer

In the direct injection nebulizer (DIN), the aerosol is also generated upon the interaction of a high-velocity gas stream with the sample liquid as in many other pneumatic nebulizers. However, this newly developed nebulizer is unique in that the sample is delivered through a narrow thin-walled highly inert capillary tube by a high-pressure gas-displacement pump (>40 kg cm\(^{-2}\)). Argon gas passes into the nebulizer tip through the narrow annular space between the sample capillary and the nebulizer tip, where a fine mist with a narrow particle size distribution is created by the interaction between the nebulizer gas and the liquid sample. The absence of large droplets eliminates the need for a spray chamber and thus the analyte is directly injected into the central channel of the ICP. The DIN is an ideal sample introduction system for samples with limited volume, as the typical consumption of the sample is only 50–100 µL min\(^{-1}\). In addition, analysis of samples for elements with a greater memory effect, such as Hg and B, can be successfully carried out by DIN because the spray chamber is eliminated and the internal volume of the nebulizer is only a few microliters.

### 3.3.4 Chemical Vapor Generation

Several elements belong to groups IVB, VB, and VIB in the periodic table, namely Ge, As, Sn, Pb, Se, Sb, Bi, and Te form hydrides, which are gaseous at room temperature. These can be generated easily from aqueous solutions in a reducing environment. The most commonly used method for hydride generation is the acid–borohydride reaction. The capability of this technique has been fully exploited in AAS, and the AAS–hydride method is now widely used on routine basis.\(^{17,18}\) Although less complicated batch processes are possible for hydride generation, continuous methods are generally preferred in ICPMS. This is because signals of shorter duration (transient response) are not suitable for multielement determination in ICPMS.

A schematic diagram of a continuous hydride generator is shown in Figure 7. The acidified sample solution and the reducing agent (NaBH\(_4\) solution) streams are pumped through narrow-bore tubing by a peristaltic pump, and combine at a capillary T-junction, where a vigorous reaction begins. The solution passes into the phase...
separator and the gaseous products alone are carried to the plasma by the nebulizer gas (Ar).

3.3.5 Electrothermal Vaporization

Electrothermal vaporization (ETV), also developed in AAS (typically known as GFAAS, graphite furnace atomic absorption spectrometry), has come into widespread use for the determination of ultratrace levels of elements with considerable success.\(^{19,20}\) The technique involves evaporation of a liquid sample directly into the plasma from an electrically heated graphite cuvette. Whereas the full atomization of the sample solution in the cuvette is the major concern in AAS, the evaporated samples could be further transported effectively (nebulizer and spray chamber are removed) into the plasma in ICPMS. Therefore, the ETV device for ICPMS and/or ICPAES\(^{21,22}\) is (Figure 8) considerably different from that used in AAS.\(^{19,20}\)

The major advantage of ETV is the very much improved sample introduction efficiency compared with the pneumatic nebulizer. The improvement in sensitivity is, therefore, an order of magnitude or more. In addition, the level of oxide ions is dramatically decreased because only the dry aerosol is introduced into the plasma. For example, considerable reduction in detection limit for \(^{56}\)Fe results from reduced spectral overlap from \(^{40}\)ArO.

3.3.6 Laser Ablation

In this technique, a laser is used as a method of volatilizing sample materials. The system is illustrated schematically in Figure 9.\(^{23}\) The sample is located in a quartz or glass cell of small volume, typically 30–100 mL, to minimize dilution of the sample vapor. The laser beam passes through the optical window and vaporizes a small part of the sample. The vapor ablated from the sample surface is then transported directly to ICP by the carrier (nebulizer) gas. When the ablated material reaches the ICP, a pulsed signal of short duration is observed similar to the peak obtained using ETV. This method allows direct analysis of the solid sample with minimum preparation. In addition, microprobe analysis can be developed when laser ablation is used with a device that controls an X-Y motion of the sample.\(^{24}\)
3.3.7 Other Techniques

One of the unique features of the ICP is its ability to accept a wide range of sample introduction systems. Modifications of ICPMS are, therefore, relatively simple and hence, hyphenated systems for specific purposes will be easily constructed. Introduction systems with greater potential are liquid chromatography (LC), and flow injection (FI).

The former (LC/ICPMS) provides information about the chemical forms, or elemental species, rather than about total amount of elements alone. In addition, on-line separation from the matrix elements and/or preconcentration are easily attainable when combined with appropriate LC systems. FI/ICPMS systems are advantageous for solutions with high dissolved salts content because only a limited amount of sample, usually 50–100 µL, is injected into a continuously flowing stream of a carrier solution of very low or no salts content.

4 SAMPLE PREPARATION

4.1 Methods of Dissolution

For the total analysis of solid samples, all the elements have to be brought into solution, although such techniques as laser ablation\(^{23,24}\) and slurry introduction\(^{12,13}\) are known to be available. Classical thermal decomposition methods (dry ashing) are not applicable for ICPMS because loss of certain volatile elements and/or contamination during the ashing procedures are rather common in these methods. As solutions of high salts content are not suitable for ICPMS, fusion methods are also not acceptable unless the analytes are subsequently separated by applying appropriate chemical techniques. A further problem associated with this method is the difficulty of obtaining high-purity fusion reagents (fluxes), such as NaCO\(_3\) and Na\(_2\)B\(_4\)O\(_7\). As a consequence, digestion with strong acids (wet digestion) is exclusively used in ICPMS, although the fusion techniques are often required to dissolve the refractory substances mentioned below. Acids of ultrahigh purity are commercially available now.

4.1.1 Open Digestion Systems

Digestion methods for plant and tissues and related materials for ICPMS are essentially similar to those already developed for other types of analytical methods, especially for ICPAES and AAS. Typically, 0.5–1 g of finely ground samples are treated with HNO\(_3\)–HClO\(_4\)
on a hot plate, followed by dissolution of the residue and dilution to 50–100 mL. The use of H$_2$SO$_4$ is not recommended because of the adverse effects of this acid in the subsequent ICPMS measurements.

The use of HF, in combination with HClO$_4$ and HNO$_3$, is a well-established method for the dissolution of samples to determine the total element content of silicate minerals and related materials, and has been extensively applied in AAS and ICPAES.\(^{(25-27)}\) Although Si is lost by evaporation of gaseous SiF$_4$ when an open system is used, no problem will arise because ICPMS is mostly applied to trace and ultratrace analysis. A problem can arise, however, because some minerals, such as chromite (FeCr$_2$O$_4$), garnet (R$^{II}_3$ R$^{III}_2$(SiO$_4$)$_3$, where R$^{II}$ may be Ca, Mg, Fe, and Mn, and R$^{III}$ may be Al, Fe, Cr and Mn), magnetite (Fe$_3$O$_4$), and zircon (ZrSiO$_4$), resist acid attack and remain undissolved even after repeated treatment. As these minerals almost always contain a wide variety of elements as “impurities” (a typical example is Hf and heavy rare earth elements in zircon), special dissolution techniques should be applied for samples containing considerable amounts of these minerals. Care is also required when the HClO$_4$–HF mixture is evaporated to dryness, because acid insoluble oxides will be formed again if too much heat is applied.

The advantages of the open digestion systems are as follows:

1. Silicon and the excess HF are easily removed by heating.
2. The final solutions are stable (silica-bearing solutions tend to hydrolyze and precipitate on standing).
3. The removal of corrosive HF allows the solution to be handled in conventional glassware for periods of at least a couple of days.
4. The salts content of the resultant solutions is low.

### 4.1.2 Closed Digestion Systems

An alternative dissolution procedure using HF is to digest the samples in a sealed Teflon vessel or “Teflon bomb” placed in a stainless steel casing.\(^{(28-30)}\) Bombs with different designs are now commercially available (Figure 10). After the addition of sample and acid, the bomb is sealed and heated in an electric oven.

The advantages of closed digestion systems over the open vessel techniques are as follows:

1. Digestion at higher temperatures is possible because the boiling point of the reagents is raised by the pressure generated in the vessel. This may shorten the time needed for decomposition and also enable the dissolution of some acid-tolerant minerals.
2. Volatile elements, such as B, Cr, As, Se, Sn and Hg, will remain within the vessel.
3. Smaller amounts of acid are sufficient for the digestion because evaporation does not occur. This lowers the reagent blank level considerably.
4. Contamination is significantly reduced because the sealed system prevents the introduction of airborne particles during decomposition.

The disadvantages are the following:

1. The maximum amount of sample that can be processed is rather limited, usually less than 0.5 g. This is especially the case when the content of organic matter in the sample is high.
2. Large amounts of H$_3$BO$_3$ should be added to complex the excess HF. This results in high salts content in the analyzing solutions.
3. Subsequent open vessel procedures are needed when the removal of Si and HF is required.

Heating needed for the acid decomposition of samples is traditionally provided externally via chemical flames or electrically on hot plates. However, methods using microwave energy for heating have been
This technique is applied most suitably to closed digestion systems because the sample solutions can be heated directly in microwave "transparent" vessels. Although domestic microwave ovens can be used successfully, purpose-built microwave digestion systems are commercially available. Very rapid heating is possible in comparison with open digestion and bomb methods because the heat is generated from inside rather than supplied from outside. A comprehensive review on this subject has been published.

5 ENVIRONMENTAL APPLICATIONS

5.1 Overview

The definition of environmental analysis seems to be not very clear. But when samples are analyzed in connection with problems associated with environmental deterioration, these activities are usually termed "environmental analysis". Therefore, the sample types considered in this section cover various different materials with diversely different natures, such as water, soils and sediments, biological samples including foods and animal tissue, and geochemical samples. Literature retrieval has shown that more than 150 reports related to environmental analysis by ICPMS were published between 1996 and 1998. The types of sample examined in the literature and their relative ratios (%) are shown in Table 1.

Extensive annual reviews of environmental analysis have been published from 1985 by the Royal Society of Chemistry (UK) in the Journal of Analytical Atomic Spectrometry. In addition to these, there have been a large number of reviews on specific types of samples and topics, as well as reviews on environmental analysis in general published in several different languages. These are soil samples, double-focusing sector field ICPMS, sediment, river water and seawater (in Japanese), trace radioactivity, boron in plants and soil, trace element species, speciation by gas chromatography (GC) ICPMS, speciation by LC/ICPMS, speciation by HPLC ICPMS, speciation by capillary electrophoresis ICPMS, ETV/ICPMS, isotope ratio analysis of environmental and biological samples (Japanese), Pu in environment and environmental samples in general (Japanese), and environmental samples in general (Japanese).

Therefore, it is not the author's intention to prepare a comprehensive review in this article but rather try to introduce several resent research works as examples.

5.2 Detection Limits and Range

The periodic table in Figure 11 shows 70 or so elements that can be determined by ICPMS and their approximate detection limits. In ICPMS, detection limits are defined as the analyte concentration equivalent to three times the standard deviation (3d) of the blank response (background) measured, in most cases, in a single ion monitoring mode for an integration time of 10 s. The standard deviation of the blank solution is calculated from 10 consecutive measurements carried out within a relatively short period (usually less than 10 min). It should be noted, however, that 5–10 times the detection limits are usually required for good qualitative measurements.

![Figure 11 Periodic table showing the detectable elements and their approximate detection limits. Unhatched elements have not been examined yet.](image-url)
The detection limits for a considerable number of elements are about 1 part per trillion (ppt). The elements not suitable for ICPMS measurements are the halides, the inert gases and atmospheric gases. Elements with a low sensitivity and/or higher detection limits fall within these groups. The so-called nonmetallic elements are not easily converted to positively charged ions. The higher detection limits observed for Si, K, Ca, and Fe are mainly due to the higher background signals caused by spectral overlaps of various molecular species originating from the matrix and/or gaseous components in the plasma (e.g. Ar, N, H and O).

5.3 Water Analysis

The types of water samples in environmental studies include lake water, river water, seawater, groundwater, and rainwater. However, assessment of water quality often necessitates analysis of related samples such as sediments, suspended materials, and aquatic biota, including algae, higher aquatic plants, insects and fish. For such samples, analytical procedures are essentially similar to those for soils and biological samples described below. Suspended materials are removed by filtration through a 0.4–0.45-µm pore size membrane filter or centrifugation.

The detection limits of ICPMS are, in general, low enough to allow the analysis of natural water samples without using preconcentration procedures. If separation and/or preconcentration steps are needed to reduce or eliminate matrix interferences (for example, seawater), wide varieties of techniques including ion exchange, coprecipitation, solvent extraction, and chromatographic resin are available.

Miyazaki and Reimer determined Pb concentrations and isotope ratios after preconcentration with a Chelex-100. A similar FI procedure has been applied to the analysis of concentrated brines and seawater. Seubert et al. described synthesis of an inert type of 8-hydroxyquinoline-based chelating ion exchanger to be used for seawater analysis. It was possible to determine several elements in seawater in the low-ppt range by on-line ICPMS detection. An FI hydride generation technique has been described for the determination of As, Bi, Sb, Se, Te, and Hg in water at ultratrace concentration levels. McLaren et al. described an on-line method for the determination of trace elements in seawater. Shabani and Masuda and Aggarwal et al. developed on-line methods for trace rhenium and sub-ppt levels of rare earth elements in seawater, respectively. Speciation of arsenic compounds in drinking water by capillary electrophoresis and hydride generation ICPMS has been reported by Magnuson et al. It was possible to speciate four environmentally significant toxic forms of As: arsenic, arsenate, monomethylarsonic acid, and dimethylarsinic acid. Ion chromatography ICPMS utilizing hydride generation with a membrane separator was also investigated by the same authors for this purpose. Interesting examples other than those described above are summarized in Table 1.

5.4 Soils and Related Materials

The first report on ICPMS appeared in 1980. Although the total number of publications on ICPMS reached more than 3500 by April 1999, rather fewer applications of ICPMS for the analysis of soil samples and related materials have been reported. These are summarized in Table 2. The high cost of the instrument appears to be the major reason preventing its widespread use among soil scientists. The price however continues to fall dramatically with increased annual production, so it might be expected that ICPMS will become one of the most widely used techniques for the determination of trace and ultratrace element concentrations, as well as for isotope ratio measurements in soil samples in the near future.

Yamasaki et al. selected about 100 soil samples in such a way as to cover a wide range of chemical as

well as mineralogical compositions and examined the detectability of elements. A large number of elements were found (levels 10 times greater than the blank) in most soil samples. These elements are conveniently classified into four Groups, as shown in Figure 12 using the periodic table.

The elements classified in Group 1 were identified for all the samples examined. The problem associated with determination of these elements (except for Cu and Zn) is that high and variable dilution ratios (100–1000 fold) must be employed to adjust the concentration of each element to the optimum range. This not only requires time-consuming manipulation but also greatly reduces the multielement capability of ICPMS.

The elements belonging to Group 2 were detected in more than 90% of the samples. The unparalleled detection power of ICPMS is clearly demonstrated by the fact that it was possible to confirm the occurrence of more than 40 elements (Group 1 + Group 2) within several minutes. In addition to these elements, those classified in Group 3 were also found in about 70% of the samples. The elements in Group 4 were detected in only less than 50% of the samples. This indicates that the contents of these elements in soil samples are generally too low (<0.1 mg kg⁻¹) for detection even with extremely sensitive ICPMS. It is apparent, therefore, that there are still a considerable number of elements for which we need adequate preconcentration and/or separation techniques to obtain reliable data on their content in soils.

6 METHOD DEVELOPMENT

6.1 High-resolution Inductively Coupled Plasma Mass Spectrometry

6.1.1 Background of Development

Although ICPMS has various advantages over other analytical techniques as mentioned previously, it has become evident that high selectivity and simplicity of spectra are not always the case. This is mainly because...
various polyatomic molecular species, originating from
gaseous components (i.e., H, C, N, O, and Ar), matrix
elements in samples, and components in acids or alkalis
used for sample dissolution are formed in spite of the
high temperature of the plasma. It is often the case
that spectra appear simple only because the commonly
used quadrupole-type mass spectrometers in ICPMS are
incapable of separating chemically different ions at the
same nominal m/z value.

The driving force behind the development of a new
type of high resolution instrument that uses a double-
focusing mass spectrometer has been the separation of
the analyte ions from the overlapping polyatomic ions
which is especially noticeable in the region between mass
40–80, that is, from $^{40}\text{Ar}^{16}O_2$ to $^{40}\text{Ar}_2$. Typical examples
of such overlapping peaks and the resolution needed for
the separation of the analyte ions are shown in Table 4.

### 6.1.2 Instrumentation

Commercial high-resolution ICPMS was first launched by
VG Elemental (now Micromass UK Ltd.) in 1988. Similar
systems were also introduced into the marketplace by two
other manufacturers (JEOL in Japan and Finnigan MAT
in Germany). In 1998, the total number of this type of
instrument working in the whole world was estimated
to be more than 200 provided by four manufacturers. A
schematic representation of the main components of the
ELEMENT, an instrument provided by Finnigan MAT,
is shown in Figure 13.

The main reason for developing the high-resolution
ICPMS was to resolve molecular overlaps caused by
matrix species. However, it has also become evident that
the detection limits of most elements are significantly
improved when this instrument is operated in the low
resolution mode because of the much lower background
signal and higher ion transmission. The low background
is because the long and curved ion flight path together
with the complex focusing elements prevent photons from
reaching the detector. The higher ion transmission is the
result of ion acceleration and efficient focusing.

### 6.1.3 Resolution and Sensitivity

Figure 14 illustrates how the signal intensity changes
with resolution. Data was obtained by aspirating the
1-ppb (parts per billion) indium (In) solution using a
USN. Signal intensity is expressed in terms of counts
per second (Hz) per parts per million (ppm) of In. The
analyzing system used in this experiment has such
excellent detection power that a signal intensity as high
as 2 GHz ppm$^{-1}$ is reached when the instrument operates
in the lowest resolution mode (i.e. with both slits opened
wide). The resolution in this mode is estimated to be
around 400. When the resolution is increased to 1500
to separate, for example, Si from $^{16}\text{O}_2$, the sensitivity
decreases to 60% of that obtained in the low-resolution
mode. If the resolution is further increased to 3500 for
the first transition elements, the signal intensity is around
400 MHz ppm$^{-1}$. At a resolution of 8500, the sensitivity
is only 2% of that attained in the low-resolution mode.

### 6.1.4 Typical Detection Limits

Detection limits of a high-resolution instrument are sum-
marized in Figure 15. These values were obtained under
essentially similar conditions to those in quadrupole-type
instruments, although sample solutions were introduced
through a USN.

As mentioned above, spectral overlaps caused by
polyatomic molecular species originating from gaseous
components and/or matrix elements are common in the
mass range of 40–80, so measurement of the first
transition elements must be carried out in the high-
resolution mode. Because sensitivity decreases sharply
Figure 14 Sensitivity versus resolution curve. Data was obtained using 1 ppb of indium (In) solution. Signal intensity is expressed in terms of counts per second (Hz) per ppm of In.

Figure 15 Typical detection limits obtained by a high resolution ICPMS. The total peak dwell times (integration times) were 5 s. Reliable values were not obtained for those elements shown in italics (Na, K, and Ca) owing to higher blank levels. Other unhatched elements have not been examined yet.

when the instrument operates in the high resolution mode, as shown in Figure 14, the detection limits of these elements were expected to be considerably higher than those of the elements for which measurements can be done in the low-resolution mode. It can be seen, however, that the detection limits of the first transition elements, except Fe, are all well below 1 ppt even in the high-resolution mode. This high value for 56Fe can be attributed to the higher total counts of the blank, presumably owing to the effect of 40Ar16O. It was not possible to obtain reliable values for Na and Ca because of a very high blank value possibly originating in the sample introduction system and/or owing to the memory effects.

With the exception of Mg, Si, P, S, Ge and As, detection limits of elements other than the first transition elements were below 0.1 ppt, and reached as low as less than 1 ppq (0.001 ppt) for some elements.

Because the instrumental conditions for the measurement of each element are different, it seems impossible to relate the detection limits to the nature of the element based on comparison of these values between different elements. There is a general tendency, however, for the detection limits of monoisotopic elements to be lower than those of other elements because the signal intensities for each isotope are, in principle, proportional to its abundance. A much higher detection limit was observed for As because it must be measured in a very high-resolution mode because of ArCl+, and the high value for Si is due to a high blank value possibly originating from the sample introduction glassware and/or a torch made from quartz. The disappointing detection limits for Ir and Pt appear to be due to higher blank signals presumably originating from the sample introduction tube made of Ir–Pt alloy. In contrast to this, the higher detection limits for P and S apparently resulted from a combination of the lower degree of ionization for these elements and the requirement for a higher resolution (i.e. around 1000) mode to be used.

6.2 Multiple-collector Instruments

The precision of isotope ratio measurements attainable by ICPMS are much poorer than those by thermal ionization mass spectrometry (TIMS), which is widely used as the benchmark method for the very precise determination of isotope ratios in such fields as isotope geology and nuclear sciences. Apparently, this limited precision is a consequence of the unstable nature of ICP. Theoretically, considerable numbers of errors caused by the instability of the ion source can be eliminated if each isotope ion is measured simultaneously by using multiple-collector systems. This type of instrument was introduced into the marketplace by VG Elemental in 1994 (Figure 16). Precision of the order of 0.03–0.003% has been reported for these instruments. (164, 165) At present, this type of instrument is provided by three different manufacturers...
and more than 40 sets of machines are working all over
the world. The advantages of this instrument over TIMS are as follows:

1. Sample preparation procedures are simplified.
2. Measurement time is much shorter (several minutes) than TIMS (typically several hours).
3. Mass bias correction can be made using separate elements.
4. Precise ratios can be measured even for transient signals originating from such techniques as ETV and laser ablation.

Another type of multiple-collector instrument with the collision cell interface (see section 6.4) has been introduced into the marketplace by Micromass UK Ltd.

6.3 Time-of-flight Instruments

Myers et al. described a novel type of ICPMS combined with a TOF mass spectrometer (ICP/TOF/MS). In the TOF instrument, separation of ions is based on the measurement of the TOF of ions of known energy over a known distance. As it is possible to measure the flight times of all the ions, TOF/MS is very efficient compared with other types of mass spectrometer, where only a very small fraction of the ions are measured in the collector system. Detection limits were from 0.4 to 2 ppb. ICP/TOF/MS is currently provided by two manufacturers (GBC Scientific Equipment Inc. and LECO Corporation).

6.4 Collision Cell Interface Inductively Coupled Plasma Mass Spectrometry

The usefulness of collision cells to attenuate polyatomic ion interferences in ICPMS has been studied by Douglas, \(^{170}\) Rowan and Houk \(^{171}\) and Bricker et al. \(^{172}\) A new type of quadrupole ICPMS equipped with a hexapole RF collision cell (Platform ICP) was launched by Micromass UK Ltd. The collision cell is placed between the skimmer cone and the quadrupole mass analyzer to reduce interference resulting from Ar-based molecular ions. The detection limits for easily ionizable elements such as Pb, In, Sr, were less than 1 ppt, and those for difficult elements including Fe, Ca, K, Cr, As and Se were around 10 ppt. \(^{173}\) A similar type of instrument (Dynamic Reaction Cell) is also provided by Perlin Elmer/Sicex Corporation. However, further work on more difficult samples seems to be necessary before the usefulness of this very new technique can be evaluated fully.

6.5 Low Sample Consumption Nebulizers

Two types of nebulizer with much lower sample uptake rate have been introduced into the marketplace. One is a high-efficiency nebulizer (HEN) provided by J E Meinhard Associates, \(^{174}\) and the other is a micro-concentric nebulizer (MCN) (Figure 17) from CETAC Technologies. \(^{175}\) The MCN comprises a nebulizer body with polyimide capillary and spray chamber end-cap adapter. The latter is used to connect the sample tubing to standard Scott-type spray chambers.

These kinds of devices including DIN (section 3.3.3), and several other prototypes not yet commercially available have clear analytical advantages for environmental samples. First, they will often be useful where the amounts of samples are limited, such as animal tissues and body fluids. Second, the reduction in sample amounts immediately results in the reduction of the analytical cost needed for sample collection and storage.

Industrial sites where residues and wastes such as slags, ashes, dust and sludges have been dumped are essential parts of the environment and of the economic structure. The amount of waste produced, distributed and deposited is constantly increasing. The wastes can contain hazardous components that pollute and endanger the environment, but they can also consist of valuable materials, which are a source of secondary raw materials. To assess the environmental risk caused by the waste, or to calculate the economic benefit of dumped material, a reliable knowledge of the waste composition is required. Waste management experience has regularly shown that conflicts and lawsuits are the result if the composition of the waste materials is difficult to determine reliably. Investigations carried out by different institutions and persons, or by the same personnel under varying conditions, will often have very different results. The measuring technology and the measuring methods cannot be the only reasons for that. Nowadays, it is possible to accurately determine chemical components in any natural concentration, and there is no problem in distinguishing the size and shape of particles down to the nanometer scale. The problems are created because the wastes are mixtures of particles and lumps which vary in size and shape as well as in chemical composition and physical properties. A waste dump with a varied production history and dumping conditions, with chemical reactions or physical changes occurring after dumping, will be heterogeneous as a rule. Therefore, the evaluation of any dump of industrial waste materials is quite difficult. To ensure that the results of evaluation are comparable, certain regulations of investigation must be followed. According to the delivery, the wastes are classified into material streams (stationary, moving or free falling), heaps delivered within containers and vehicles, and free-standing heaps. As it is economically unjustifiable to investigate the entire waste dump, subsets of material (called samples) must be taken from the stream, the container or the heap in order to determine the measurements of interest. In doing this, rather a lot of errors can be made. Therefore, the errors that exist are frequently caused by unobjective sampling and improper handling of the sample material. However, a false estimation can also be made by evaluating reliable data using unsuitable statistical methods.

The present contribution takes up this problem. An industrial waste dump and a contaminated site were chosen as examples, and proven sampling regulations were applied. The applicability of known statistical and geostatistical methods developed for homogeneous granular bulk solids and uniformly contaminated soils to the evaluation of extremely heterogeneous waste dumps and nonuniformly contaminated industrial sites is shown.

1 INTRODUCTION

The evaluation of heterogeneous granular and lumpy industrial wastes by sampling and statistical data analysis is still a problem worldwide. First of all the sample must be obtained objectively, and secondly the sample material must be properly stored and preserved.

Sampling is objective under the following conditions:

- the sampler (person taking the sample) knows what material is being presented;
- the sampler knows the aim of the investigation;
- the sampler acts strictly according to certain regulations to reach the aim of the investigation;
- the sampler justifies these regulations to himself and to the client, and considers that the method of sampling prescribes how to evaluate the results.

For homogeneous granular mixtures and mining goods such as powders, sand, gravel, salt, iron ore and solid fuels, these problems have been thoroughly investigated. There are detailed instructions for sampling, for common procedures between the sampler and the laboratory, and for agreement between contracting parties.\textsuperscript{1–3} The
evaluation of the results depending on the sampling scheme is controlled by mathematical models. The handling of instructions and methods is justified by national and international standards, the applications of which are obligatory within the framework of the respective economic and legal systems. The regulations, mathematical models, instructions and standards for sampling are based on the assumption of a small grain size range and a uniform particle shape. The methods of data analysis are based on mathematical statistics and geostatistics. They suppose a homogeneous isotropic material with uniform variation of the characteristic under consideration.

In contrast, industrial wastes can be extremely heterogeneous with respect to their material composition and to the degree of mixing of the individual portions. The concentration of harmful substances or the content of valuable material can vary considerably depending on the origin of the waste. Waste can consist of particles and lumps, with extreme distributions of particle size and shape. Characterization of the size and shape of lumps is not yet regulated by specific measures and dimensions. Within an individual lump, several components can be intermixed, melted, screwed, welded or stuck together. Recycled products, wastes and scraps can also contain lubricants, cooling agents, brake fluids and other substances which make the material sticky, lumpy and greasy.

Pollutants in contaminated sites and soils can occur in complicated, partly volatile compounds which demand a lot from the handling and analysis of the samples. Plants and animals can also serve as indicators of pollution. They require specific goals for sampling and special equipment for trace analysis as well as particular care in sample preparation and sample pretreatment.

As a consequence, the assumptions underlying the geostatistics are not always correctly fulfilled by industrial waste dumps. There are still no special regulations expressly valid for the sampling of heterogeneous waste materials, and no statistical models specifically evolved for the evaluation of data obtained from wastes. Further research work is necessary in this field. Previously, recommendations and statistical methods which are satisfactory or promising for other solids systems that are structurally or materially similar to the respective waste dump have been used.

In the present article, a slag heap from Saxony, Germany, is used as an example in the application of sampling regulations and of known statistical methods for homogeneous bulk solids to the evaluation of extremely heterogeneous coarse grained and lumpy solids systems. The article also deals with the problem of the composition of a material being changed by improper handling after sampling. Soil samples taken from a mercury-contaminated industrial site are used as an example. It is shown that the mercury content detected by analysis is systematically decreased by improper preservation of the samples. Frequently, soil pollution is influenced by the geogenic background; it varies significantly as the location within the site is changed and as the sampling depth is varied. The investigations are planned in order to quantify the systematic error of sample preservation and to simultaneously distinguish the sample value from the geogenic background. For this reason, a statistical approach is proposed.

2 BASIC PROBLEMS OF SAMPLING AND ANALYSIS OF INDUSTRIAL WASTES AND WASTE DUMPS

The aim of sampling and analysis is to obtain a representative evaluation of the waste material. In doing sampling and chemical or granulometric analysis, two opposing principles have to be brought into line. On the one hand, the sample should be as large as possible, but this is not economical or practical. As a compromise, a sample having at least a certain minimum mass is required. The minimum sample mass is established according to certain mathematical models or empirically founded rules. This quantity increases as the particle size increases and as the reliability, which is required to describe the composition of the entire waste material by sample, enlarges. On the other hand, the amount of material needed for chemical or granulometric analysis is very very low. To get a final sample for analysis, the composition of which substantially represents the properties of the original sample material, very expensive sample preparation procedures must be applied such as comminution, homogenization (by mixing or melting), and dividing and reducing of the material. With these procedures, some errors are unavoidable. But sample preparation is not the only source of errors which influence the results of the investigation. All procedures, from sample selection up to statistical data analysis, cause unavoidable errors. Their effects on the evaluation are estimated as follows.

1. Sampling is the selection of samples from the waste material. Error at this stage is caused by global and local variations of the waste material and can amount to up to 1000% of the true value.

2. Sample pretreatment includes all events which can occur as a result of the handling of the samples, from their selection until preparation for analysis, and which cause the original properties to be changed. Volatilization or adsorption of components are examples of processes by which the material is
3. **Sample preparation** includes the processes of comminution, homogenization, division and reduction of the original material to establish the final sample for analysis. The maximum error of sample preparation is between 100% and 300% of the true value.

4. **Instrumental measurement**; this error is vanishingly small compared with those from the preceding steps, and amounts to a maximum of 2–20% of the true value.

5. **Data analysis** is applied to solve the scientific problem using all the data available. If an incorrect mathematical model is used for this purpose it can cause an error up to 50%.

A simplified scheme of the unavoidable errors caused by the different steps in the material evaluation is shown in Figure 1.

Consequently, false sampling and gross defects in handling the material may influence the results of the investigation more seriously than the instrumental measurements. Generally, the following principles are valid:

- if the sampling is false, everything is false;
- if the measured values are right, but the method of data evaluation is unsuited for the intended purpose, the results of the evaluation may be doubtful.

To limit the errors of evaluation, every step from sampling up to data analysis must be carried out strictly according to certain regulations and specific mathematical methods. To plan the investigation, the following questions are asked.

1. What is the special purpose of the investigation and what is already known about the waste dump or the industrial site?
2. What additional information is striven for?

To answer these questions, the following parameters are established:

1. The sampling design, which defines the time, the location and other conditions of sampling that are essential for the characterization of the waste material (dump, stream, site). When planning the sampling conditions, the sampler has to imagine an appropriate structure for the object of investigation.
2. The number of samples.
3. The minimum mass of an individual sample and the gross sample mass.
4. The sample handling procedures, which are necessary to ensure that the data are of the required quality.

5. The quantity to be measured.
6. The methods of statistical data analysis. These methods have to be suitable for the sampling design.

The success of sampling and data analysis is measured by

- the accuracy (precision)
- the confidence (trustworthiness) and
- the reliability

of the waste characterization.
The gist of these criteria is explained as follows.

1. Accuracy or precision: Let \( \mu \) be the true value of a characteristic of interest (e.g. the content of a hazardous component). This value is not known and can only be estimated from samples. An error \( |\bar{Y}_n - \mu| \) is made by using the mean value \( \bar{Y}_n \) obtained from \( n \) samples instead of the true value \( \mu \). This error is called the accuracy of estimation (accuracy of prediction) of \( \mu \) by the mean \( \bar{Y}_n \). In practice, an upper limit \( \varepsilon_0 \) of \( |\bar{Y}_n - \mu| \) is prescribed. The limit \( \varepsilon_0 \) is termed the maximum admissible error of the mean.

2. Confidence: Because the accuracy of estimation \( |\bar{Y}_n - \mu| \) is a random variable, a probability \( \beta \) must be given, where the relation \( |\bar{Y}_n - \mu| \leq \varepsilon_0 \) is valid. The value \( \beta \) is called the confidence probability of the admissible error of the mean. In practice, a \( \beta \) value between 0.90 and 0.99 is recommended.

3. Reliability: When using inaccurate data, a certain risk (e.g. expected loss of confidence, additional costs) must be taken into account. If the risk associated with a data set is acceptable, it is called a reliable data set.

In the following section, some experiences in sampling and sample pretreatment are presented.

3 SOME EXPERIENCES

3.1 Geostatistical and Statistical Evaluation of a Heterogeneous Industrial Site

3.1.1 Object Investigated

The slag heap of a smelting plant at Freiberg in Saxony, Germany, was investigated. Further studies have also been carried out.\(^{14,18,19}\) Rasemann and Markert\(^{14}\) have explained the methodical concept of investigation and the statistical methods used for evaluating the results of sampling and analysis. In this article some of the practical conclusions reached in the papers mentioned with the help of additional data have been proven to be true. The slag was a by-product from the thermal processing of zinc blende (ZnS) ore concentrates. The concentrates were roasted in a fluidized-bed roasting furnace which produced calcined zinc oxide and sulfur dioxide in the roaster gas. The roaster gas was used to produce sulfuric acid, which was used to leach the calcine. The leaching was followed by separation into solid low-grade leaching tailings and high-grade leachate. The leachate was an electrolyte, from which the zinc was cathodically precipitated. The leaching tailings consisted of the remaining portions of zinc and other valuable components such as lead, cadmium and iron. The tailings were washed and dried, and then thermally processed in a rotary furnace to extract the metals. Fine coke was added to reach a high furnace temperature and to reduce the metal oxides. The residue of this process, the rotary furnace slag, was continuously discharged, then cooled, granulated and transported to a slag pit. Finally, the slag was moved by truck from the pit to the dump.

The leaching tailings processed were delivered from different factories so they varied in composition over the entire operating period. Consequently, the rotary furnace slag was composed of widely varying portions of \( \text{SiO}_2 \) (10–20%), \( \text{FeO} \) (15–30%), \( \text{CaO} \) (10–15%), \( \text{Al}_2\text{O}_3 \) (about 6%), \( \text{C} \) (10–45%), \( \text{S} \) (about 6%), \( \text{Zn} \) (1–5%), \( \text{Pb} \) (0.1–2.5%) and \( \text{Cu} \) (0.3–0.6%). Cadmium and arsenic also occurred in low concentrations. The high carbon content resulted from unburnt coke. After the slag was dumped, the fine coke in the heap was carbonized at low temperatures, parts of the normally grained slags were incinerated, the heap caved in and the slags were sintered to blocks here and there. The very heterogeneous slag heap thus consisted of blocks and lumps of slag and of coarse-grained bulk material. The chemical composition was extremely varied. After the first inspection, the heap surface was distinguished by three regions (Figure 2):

- normally grained slag which was partly burnt
- very incinerated regions
- solid blocks and lumps of sintered slag.

The heap extended over an area of 1.6 ha and it was between 4 and 12 m high. The total mass was about 80 kt.

3.1.2 Sampling Strategy

3.1.2.1 Sampling Pattern, Number of Samples and Mass of an Individual Sample

For evaluation, the area was covered by a regular grid consisting of 60 points.

Figure 2 View at the rotary furnace slag heap of the smelting plant at Freiberg in Saxony.
forming equilateral triangles with sides of 10 m. The efficiency of such a grid is evaluated as follows.\(^{(20)}\) If there is no information about the spatial distribution of contaminants or valuable components, the largest uninvestigated subsection of the grid may be a criterion for the probability of incorrect evaluation. To compare different grids, such a subsection is defined as the area of a circle drawn to connect adjacent grid points. A grid with minimal uninvestigated subsections compared with any other geometric pattern is assumed to be optimal. This condition is found to be fulfilled by a grid of equilateral triangles. A square and an equilateral triangle, as respective units of a regular grid, are compared with each other in Figure 3. The squared triangle, as respective units of a regular grid, are optimal. This condition is found to be fulfilled by a grid of equilateral triangles (b).

Figure 3 Area of the circumscribed circle and the corresponding radius belonging to the cells of a rectangular grid (a) and of a grid of equilateral triangles (b).

inside diameter of the percussion coring tube (40 mm) and an average bulk density of 1.1 g cm\(^{-3}\), the mass of an individual sample was about 1.4 kg. In practice, a lower sample mass caused by unavoidable core loss during boring has been taken into account. Because of the high iron content and the predominantly grained structure of the slag, the masses and the numbers of samples were compared with the International Sampling Guidelines for Iron Ores, ISO 3081.\(^{(24)}\) and with the German standard for sieve analysis from the Deutsches Institut Für Normung (DIN) 18123.\(^{(25)}\) According to these standards, the required sample mass and the minimum number of samples depend on the maximum grain size, the grain size of the sieve curve at 5% oversize.

In the case of the granular rotary furnace slag, a maximum grain size of 2.5–25 mm was obtained using sieve analyses of the eight surface samples from each of the ten sampling points. Taking these data as a basis, DIN 18123 requires a minimum mass for an individual sample of 0.2–3 kg, (see Table 1). The ISO 3081 standard calls for a mass of 0.3–4 kg under these conditions (see Table 2). In addition, this standard prescribes 180 individual samples for a test material mass of 70–100 kt. Following these recommendations, six or seven samples

from each of the 18 grid points of the percussion coring investigation are necessary, in addition to the 56 surface samples. Therefore, the sampling strategy chosen by us did not contradict the regulations now valid for bulk solids handling.

Appropriate rules are lacking for sampling extremely heterogeneous wastes, as has been repeatedly emphasized. General guidelines are being developed for sampling wastes but at most they contain only rough information. An overview of the European standards in this field is given by Knoop. These standards require chemical analyses, which unfortunately have not yet been controlled by corresponding regulations and European standards. Until now, regulations for the chemical analysis of wastes have been used, which have been developed only for water, soil, sludge and sediments or for materials handled in the fuel and mineral oils industry. However, there are exact regulations regarding the chemical analyses of contaminated soils, such as the German Deutsche Einheitsverfahren (DEV) standards for water, sludges and sediments, but rules for the sample mass and the number of samples at contaminated sites are not included. The guidelines only contain general information. Consequently, the legal status of a person doing sampling (a sampler) is quite a problem. For a detailed consideration of this aspect, consult Krutz and Niessing. The judicial consequences resulting from incorrect decisions by the sampler have been discussed in detail.

For the sample mass, the German guideline and PN 2/78K of the Länderarbeitsgemeinschaft Abfall (LAGA) require that the minimum mass of an individual sample (in kg) is 0.06 times the maximum grain size (in mm). In the present situation (a maximum grain size between 2.5 and 25 mm), a minimum sample mass of 0.15–1.5 kg is recommended. This guideline also contains instructions for the number of samples required depending on the range of maximum particle sizes, the mass of the consignment and the delivery of the waste (see Table 3). Following these instructions, a maximum of 15 individual samples should be taken. Of course, this number is too small in the present case. However, the requirements of the German TA Abfall (Technical Instructions for Wastes) are even more unrealistic. The TA Abfall modified and simplified the sampling instructions of the LAGA guideline PN 2/78K as follows. First, the waste classes “delivered within containers” and “delivered without containers” are distinguished. Second, waste delivered without containers is classified by appearance, as homogeneous or heterogeneous. This places the rotary furnace slag in the class of “heterogeneous wastes being delivered to the dump without containers”, and therefore one individual sample of 1 kg mass per 5 t waste must be taken. For a slagheap of 80 kt total mass, 16 000 samples and a total sample mass of 16 000 kg would be necessary. This is a completely unreasonable recommendation.

3.1.3 Sample Preparation

3.1.3.1 Chemical Analysis and Granulometric Analyses

Each individual sample was prepared in its final form by homogenization, splitting and reducing. The splitting and reduction involved a three-fold coning of the sample material and subsequent quartering of the final cone using a splitting cross. The two opposite quarters of the cone were used as final samples for chemical and granulometric analyses. The quarters were weighed, and the concentrations of certain chemical components and their elution behaviors were obtained using the DEV standards for water, sludges and sewage. To determine the ignition loss, a German standard for foundation testing was applied. An overview of the DIN standards and the related United States Environmental Protection Agency (USEPA) standards applied for the investigation of waste is given in Table 4. Further details have been provided by Hein and Kunze. The concentrations of the heavy metals Fe, Zn, Pb, Cu and Cd and the As content were analyzed by acid decomposition and subsequent AAS. The S content was determined by an oxidizing melting decomposition with Na2CO3/K2CO3 + Na2O2 according to DIN 38405, part 5. The sulfur compounds were converted to water-soluble sulphates, and the barium chloride added to precipitate the sulphates was quantitatively measured by weighing. The ignition loss, a measure of the combustible matter, was determined at temperatures of 550 °C and 1000 °C, according to DIN 18128. Additionally, the grain size distribution was obtained by sieve analysis following DIN 18123.

in order to provide all the chemical and physical characteristics needed. The strategy used for a percussion core sample with a mass between 400 and 900 g is shown in Figure 4. Another variant for samples with a mass greater than 900 g was covered previously. The preparation and analysis schemes used for repeated surface sampling and for a single sampling of surface points, respectively, are shown in Figure 5. According to these schemes, the grain size distribution and the ignition loss were determined for the respective first and fourth quarters of the eight individual samples from ten surface points, as a first step. Afterwards, the residuals of the handled first and fourth quarters and the untouched second and third quarters of these eight samples were mixed, and a composite sample was obtained. Finally, the composite sample was prepared and analyzed as a single surface sample. In this way, 10 composite samples and 46 single surface samples were investigated.

3.1.4 Statistical Analysis of Data

3.1.4.1 Geostatistics The chemical composition of the rotary furnace slag was evaluated from the original surface sampling data and from the percussion coring data obtained at fixed depths. To explain the spatial variability of the chemical components, variograms were constructed. The technique of point kriging was used to predict additional values of these quantities at points inaccessible for sampling and observation.

Let $G$ be the set of all possible points of the slagheap. Both the construction of the variogram and the technique of kriging are based on the proposition that for any measuring quantity $Y_t$, $t \in G$ at a point $t$ in $G$ is a regionalized variable. Following this theory of the regionalized variable, $Y_t$ is locally a random variable, and the set of all measuring quantities $\{Y_t\}_{t \in G}$ globally describes a random field. The random field is characterized by its expected values $EY_t$ at points $t$ and by the covariances $\text{cov}(Y_t, Y_{t+\tau})$ which describe the correlation between two measuring quantities obtained in the different locations $t$ and $t+\tau$ of the heap $G$. This random field is assumed to have second order homogeneity, i.e. the expected value of any measuring quantity $Y_t$ in the total heap $G$ is equal to a constant $\mu$. The covariance $\text{cov}(...) \text{ observed in a particular direction does not depend on the absolute locations } t \text{ and } t+\tau, \text{ but is a function only of the distance } \tau \text{ between the locations. This is mathematically expressed by Equations (1) and (2).}$

$$EY_t = \mu \quad \text{for all } t \in G \quad (1)$$

$$\text{cov}(Y_t, Y_{t+\tau}) = E[(Y_{t+\tau} - \mu)(Y_t - \mu)]$$

$$= C_Y(\tau) \quad \text{for all } t \in G \quad (2)$$

$C_Y$ is called the covariance function of the random field.
Figure 5 Scheme of preparation and analysis in repeated surface sampling and single sampling of surface points.
3.1.4.2 The Variogram  Because the variances \( D^2Y_t \) and \( D^2Y_{t+\tau} \) are equal to the covariance \( C_Y(0) \) at a distance 0, the assumptions of homogeneity in Equations (1) and (2) respectively imply the following relationship between the variance and the covariance (Equation 3):

\[
V(\tau) = E[Y_{t+\tau} - Y_t]^2 = E[(Y_{t+\tau} - \mu) - (Y_t - \mu)]^2
= E[Y_{t+\tau} - \mu]^2 + E[Y_t - \mu]^2 - 2E[(Y_{t+\tau} - \mu)(Y_t - \mu)]
= 2[C_Y(0) - C_Y(\tau)]
\]  

(3)

The function \( V \) is called the variogram function of the random field, and it is twice the semivariogram function \( \gamma \), as shown in Equation (4).

\[
\gamma(\tau) = 0.5V(\tau) = C_Y(0) - C_Y(\tau)
\]  

(4)

In the following, the variance \( D^2Y_t = C_Y(0) \) is represented as the simplified term \( S_Y^2 \).

The variogram function is a continuous one. Usually, this function is not immediately known and only its estimation at discrete distances is available (called the empirical variogram function). This estimation is obtained as follows. Let \( j \) and \( j + \tau \) be any locations and \( Y_j \) and \( Y_{j+\tau} \) the corresponding measurable values in these locations, respectively. Then, the value of the empirical variogram function at the distance \( \tau \) is given by Equation (5).

\[
\hat{V}(\tau) = \frac{1}{n(\tau)} \sum_{i=1}^{n(\tau)} [Y_{i+\tau} - Y_i]^2
\]  

(5)

Here, \( n(\tau) \) is the number of pairs of measuring values obtained at a distance \( \tau \) from each other. Sufficiently accurate estimations of the variogram function must be based on a large number of data pairs. At least 50 data pairs are necessary as a general rule. For example, in a pattern of \( n_0 \) points arranged as \( k \) equilateral triangles, whose sides are \( \tau = \tau_{\text{min}} \) long (\( \tau_{\text{min}} = 10 \text{ m} \) for the surface sampling and \( \tau_{\text{min}} = 20 \text{ m} \) for the percussion coring) exactly \( n(\tau_{\text{min}}) = n_0 + k - 1 \) pairs of points are available for the variogram estimation at the minimum distance \( \tau = \tau_{\text{min}} \).

The empirical variogram function was fitted to an appropriate theoretical model to evaluate the spatial variability. The appearance of a variogram is characterized by the following structural parameters of the model:

- \( V_{\text{total}} \) = the total variance, calculated as the mean squared deviation of all the data from the overall mean;
- \( C_0 \) = the nugget effect describing the maximum variance of immediately adjacent measuring quantities (it is caused by the error in sampling and by the spatial variability in the microscale region of the site to be investigated);
- \( a \) = the range (correlation length, radius of influence), i.e. the minimum spatial distance between uncorrelated measuring quantities; \( S_Y^2 = C + C_0 \) = the sill, i.e. the maximum variance of uncorrelated measuring quantities; \( \tau = \tau_{\text{lag}} \) = the spatial distance between subsequent values of the variogram function.

These parameters occur in different models. With chemical data from contaminated soils and waste sites, the spherical model (cubic model, Matheron’s model) is frequently used successfully (Equation 6).

\[
\gamma(\tau) = \begin{cases} 
0 & \text{for } \tau = 0 \\
C + \frac{3}{2} \frac{\tau}{a} - \frac{1}{2} \left( \frac{\tau}{a} \right)^3 + C_0 & \text{for } 0 < \tau \leq a \\
C + C_0 & \text{for } \tau > a
\end{cases}
\]  

(6)

In addition to the parameters explained above, \( S_Y^2 = C + C_0 \) = the sill and \( C \) = the partial sill. For \( \gamma(\tau) \rightarrow 0 \), as \( \tau \rightarrow 0 \), then \( C_0 \) = the nugget effect (named by Matheron). This is because it is believed that a variation at very small distances (microscale variation) caused by small nuggets generates a discontinuity at the origin of the data. But the only possible reason for such a phenomenon is an error of observation in both sampling and chemical analysis. Hence, the nugget effect is unverifiable without samples that are very close together. Following this idea, eight surface samples were taken from each of ten points of the slagheap. The mean squared deviation of the replicate values at a sampling point from the respective mean is an estimation of the variance of the sampling error. The error in chemical analysis is mostly assumed to be negligible without investigating the measuring process. In geostatistics, the nugget effect is determined by extrapolating variogram estimates from lags closest to zero. Its calculation is implemented in common geostatistical software following the recommendations of Cressie. A more rigorous presentation of the nugget effect and its partitioning is available.

An appropriate approximation of the sill \( S_Y^2 = C + C_0 \) is given by the sample variance in Equation (7),

\[
S_n^2 = \frac{1}{n - 1} \sum_{i=1}^{n} (Y_i - \bar{Y}_n)^2
\]  

(7)

which is calculated on the basis of the total amount of \( n \) data of the series of measuring values, where \( \bar{Y}_n \) is the overall mean.

Besides the spherical model, various parametric variogram models are applied in environmental science and pollution research. The following two basic isotropic models are considered in terms of the semivariogram:
linear and exponential. They also include a possible nugget effect, as in the spherical model. A linear or an exponential variogram is recommended if there is a trend in the spatial behavior of the measuring quantity and if there are local anomalies in the chemical composition, or if there are polymodally or asymmetrically distributed measuring values.

The linear model is given by Equation (8)

$$\gamma(\tau) = \begin{cases} 0 & \text{for } \tau = 0 \\ C_0 + b_1|\tau| & \text{for } \tau > 0 \end{cases}$$

where $b_1 \geq 0$ is the slope of the function which holds when $C_0 \geq 0$.

The exponential model is given by Equation (9)

$$\gamma(\tau) = C_0 + C_e \left( 1 - \exp \left( -\frac{\tau}{a_e} \right) \right)$$

for $\tau > 0$ with parameters $C_0 \geq 0$, $C_e \geq 0$, and $a_e \geq 0$.

The isotropic variogram models described above (spherical, linear and exponential) have been successfully used to obtain an informative cartography of spatial heterogeneities of chemical pollutants in agricultural soils near industrial sites.\(^{(44-46)}\) The influence of the sampling distance on the estimation of the nugget effect has been investigated.\(^{(47)}\) The graph of the variogram function, the variogram, is used for practical conclusions. It gives more detailed information regarding the range of correlations and the magnitude of the local and global variability in the directions of investigation. For an anisotropic object of investigation, there are different variograms in different directions. Typical effects of anisotropy on the ranges found in the Saxon slagheap example have been presented.\(^{(18,19)}\)

### 3.1.4.3 Point Kriging

Geostatistics uses the technique of point kriging to calculate additional data at points inaccessible for sampling. The main principle of point kriging is to estimate the value $Y(t_0) = Y_{t_0}$ of the regionalized variable at an uninvestigated point $t_0$ as the weighted mean $\overline{Y}(t_0)$ of $n$ measuring values $Y_{t_i}$ observed at points $t_i$, where $i = 1, 2, \ldots, n$ (Equation 10)

$$\overline{Y}(t_0) = \sum_{i=1}^{n} w_i Y_{t_i}$$

The weights $w_i$ are determined by side conditions which state that the expected value of $\overline{Y}(t_0)$ equals the unknown $Y(t_0)$, and that the variance of prediction of $Y(t_0)$ by $\overline{Y}(t_0)$ is as small as possible. The estimate $\overline{Y}(t_0)$ of $Y(t_0)$ is unbiased, as shown in Equation (11), because

$$E \left[ \overline{Y}(t_0) - Y(t_0) \right] = 0$$

Equation (12) then holds because of Equation (10),

$$E \left[ \sum_{i=1}^{n} w_i Y_{t_i} - \sum_{i=1}^{n} w_i Y_{t_i} \right] = \sum_{i=1}^{n} w_i E(Y_{t_i} - Y(t_0))$$

and Equation (13) follows because of Equation (1).

$$E \left[ \sum_{i=1}^{n} w_i Y_{t_i} \right] = \mu \sum_{i=1}^{n} w_i$$

Because $E \left[ \sum_{i=1}^{n} w_i Y_{t_i} \right] = \mu$ holds, the weights have to fulfill the side condition shown in Equation (14).

$$\sum_{i=1}^{n} w_i = 1$$

The variance associated with predicting unknown values using the weighted mean of known values is given by Equation (15).

$$\sigma^2_{prediction} = E \left[ \overline{Y}(t_0) - Y(t_0) \right]^2 = D^2 \overline{Y}(t_0)$$

This variance can also be written in the form shown in Equation (16).

$$\sigma^2_{prediction} = \sum_{i=1}^{n} \sum_{j=1}^{n} w_i w_j \text{cov} (Y_{t_i}, Y_{t_j}) - 2 \sum_{i=1}^{n} w_i \text{cov} (Y_{t_i}, \overline{Y}(t_0)) + \text{cov} (\overline{Y}(t_0), \overline{Y}(t_0))$$

Equation (17) follows from Equation (16), because of the requirement of homogeneity (Equation 2),

$$\sigma^2_{prediction} = \sum_{i=1}^{n} \sum_{j=1}^{n} w_i w_j C_Y (|t_i - t_j|) - 2 \sum_{i=1}^{n} w_i C_Y (|t_i - t_0|)$$

(\text{where } C_Y \text{ is the covariance function}).

The requirement to minimize the prediction variance under the side conditions in Equation (14) provides a system of $n + 1$ linear equations in the weights $w_i$ desired (Equation 18).

$$C_Y (|t_1 - t_1|) \ 1 \ 1 \ \ldots \ 1 \\
C_Y (|t_1 - t_2|) \ 1 \ 1 \ \ldots \ 1 \\
\vdots \ \vdots \ \vdots \ \ldots \ \vdots \\
C_Y (|t_n - t_1|) \ 1 \ 1 \ \ldots \ 1 \\
C_Y (|t_n - t_2|) \ 1 \ 1 \ \ldots \ 1 \\
\vdots \ \vdots \ \vdots \ \ldots \ \vdots \\
w_1 \ C_Y (|t_1 - t_0|) \ 1 \ 1 \ \ldots \ 1 \\
w_2 \ C_Y (|t_2 - t_0|) \ 1 \ 1 \ \ldots \ 1 \\
\vdots \ \vdots \ \vdots \ \ldots \ \vdots \\
w_n \ C_Y (|t_n - t_0|) \ 1 \ 1 \ \ldots \ 1$$

\begin{align*}
\lambda \ &= \ 1
\end{align*}
This equation system has a unique solution if the determinant of the system matrix on the left of Equation (18) is nonzero. The complementary quantity \( \lambda \) is the Lagrange parameter, associating the weights \( w_i \), (where \( i = 1, 2, \ldots, n \)), with the side condition that they total 1. The prediction variance has the value given by Equation (19).

\[
\hat{\sigma}_{\text{prediction}}^2 = C_Y (|t_0 - t_0|) - \sum_{i=1}^{n} w_i C_Y (|t_i - t_0|) - \lambda
\]  

Because of Equation (4), the covariance function \( C_Y \) is expressed by either the semivariogram function \( \gamma \) or the variogram function \( V \). Therefore, the kriging technique which generates additional data in inaccessible points serves a double purpose: (1) to provide the data necessary to model the spatial variability of the measurable quantities in the object investigated; and (2) to formalize the estimated variogram function.

The step-by-step realization of the strategy “estimation of the variogram function, calculation of new values by point kriging” leads to a theoretically sufficient number of data, but only the empirical variogram allows us to conclude whether or not the results of the kriging are useful. In the case of an abnormal variogram function contradicting the theoretical assumptions of a homogeneous random field, the geostatistical theory is insufficient. The variogram function is abnormal if its values decrease as the distance increases after an increasing period or if there is generally no recognizable structure. An interpretation of the calculated results is irresponsible in such cases.

Frequently, no distinction is made between the terms variogram and semivariogram because the connection between them is clearly defined by Equation (4).

For a detailed derivation and discussion of kriging techniques, consult Journel and Huijbregts and Cressie. A concise presentation of geostatistics in general and kriging in particular is given by Journel and Cressie. The largest range was observed in the east-north-east direction, with the ratio of the largest range to the smallest one amounting to 2.6. The figures written near the function points of the variogram represent the respective numbers of pairs of measuring values used to calculate the corresponding function value at the respective distance (Figure 6a). The three-dimensional graph of the data visualizes the spatial distribution of the iron content on the heap surface (Figure 6b). The local anomalies characterize extreme iron contents and they clearly stand out against the globally inherent iron distribution on the heap surface. The anomalies reflect the original data obtained at the sampling points, but the overall spatial variability is easily recognizable.

In contrast, useful empirical variograms were obtained for both the sulfur content and the zinc content in all directions by a stepwise change of the directions investigated. In principle, the three-dimensional graphs of both the sulfur and zinc contents are similar to that of the iron content, in some directions. This may be caused by the mineralogical composition of the thermally processed ore concentrates, the residue of which is the rotary furnace slag.

Furthermore, the following effect was observed in the spatial variability of the sulfur and the zinc contents. All the variograms have one and the same sill but different ranges depending on the direction searched. The set of ranges forms the boundary points of an ellipse in the given coordinate system. This effect is called a geometric anisotropy. The largest range was observed in the east-north-east direction, with the ratio of the largest range to the smallest one amounting to 2.6. The direction of the largest range and the ratio were used to transform the coordinates of the investigated area so that the transformed area was considered isotropic and consequently fulfilled the assumption of the kriging technique. Convincing three-dimensional graphs of the original data and the kriging values were obtained.

As for the lead content, semivariograms with no valuable structure or at least an untypical appearance were calculated. It was proved that the empirical variograms are fitted by a set of spherical model functions whose parameters may vary over wide intervals without any significant change in the goodness of fit. For a detailed discussion of this fact, see Rasemann and Herbst.

The arsenic and cadmium contents also proved to be untypical of the chemical composition of the slagheap. The semivariograms calculated were either difficult to
Figure 6 Geostatistical evaluation of the iron content using the original data from surface sampling in the west–east extension of the slagheap. (a) Empirical semivariogram and corresponding spherical model fitted with a nugget variance of 3.0%², a sill of 20.0%², and a range of 30 m, respectively; (b) three-dimensional graph obtained after point kriging.

evaluate or were useless. There was neither a preferred direction of variability nor any geostatistical similarity between different directions. The parameters of the fitted semivariograms varied considerably from distance to distance and from direction to direction without a recognizable systematic structure. The anomalous variograms of the arsenic and lead contents can be explained by local nested concentrations of these pollutants on the heap surface. Anomalies formed by environmental influences occurred after dumping of the slags. Thus, because of the high concentration of unburnt carbon, the slag was carbonized at a low temperature and volatile components such as arsenic and lead sublimated on the surface and formed corresponding chemical compounds. The frequency distributions are also polymodal and asymmetric. The lead content distribution of a normal slag is shown in Figure 7, as an example.

The ranges of the semivariograms were mostly larger than the minimum sampling distance of 10 m, i.e. more samples than needed for a simple random sampling analysis using correlated data were taken. The available data generally gave grounds for a geostatistical analysis, but the number of values was insufficiently small in some
cases, and the errors expected were then too large for a reliable interpretation.

**Percussion Coring.** One sample was taken at every meter depth from percussion coring wells at 18 points of a regular pattern of equilateral triangles whose sides were 20 m long. The chemical components of samples from the same depth interval were geostatistically evaluated. The iron, copper, sulfur, cadmium, arsenic, and lead contents and the ignition loss were investigated. In general, both variograms and kriging structures obtained were similar to those for the surface sampling. In the following, some results from the 1–2 m depth interval are discussed.

The variograms and three-dimensional graphs obtained after kriging were especially valuable for the iron, sulfur and zinc contents in the west–east extension. In this orientation, structures of the spatial variability were traced even from the heap surface. But there are also directions in which the variograms are completely useless. To demonstrate this, the results of geostatistical evaluations of the zinc content obtained in the northerly direction are discussed. In Figure 8(a), an empirical semivariogram is presented. It was calculated only on the basis of the original data obtained from percussion core samples taken from 18 pattern points at a depth of 1–2 m. Between 2 and 17 pairs of measuring values were available to construct the points of the empirical

![Figure 8](image-url)
variogram. Because of the relatively small number of original data points, the error in the calculated results was correspondingly large. A spherical model with a nugget effect $C_0 = 1.32\%^2$, a partial sill $C = 3.74\%^2$, and a range $a = 27.75$ m was fitted. Using this model, point kriging was carried out. Figure 8(b) represents the corresponding three-dimensional plot. Obviously, this plot reflects only the original data and those in the neighbourhood of the sampling points, in principle. However, the data from this neighbourhood were inaccurate, because the distances between the original points were so large that the kriging procedure only provided an interpolation between the original data and the overall mean. This conjecture has been examined previously for a similar situation involving the evaluation of the iron content.(14,19) Therefore, for a mainly heterogeneous slagheap with wide distances between adjacent sampling points, the technique of point kriging must not be used to model the spatial variability of the chemical composition.

The spatial variability of the sulfur content was accurately represented by geostatistical methods. Structures obtained were similar to those of the surface sampling. No systematic dependence of the original data on their spatial allocation was observed for the cadmium content. Consequently, empirical (semi)variograms were obtained which could not be fitted by a single-value theoretical model function.

The use of percussion coring to evaluate the spatial distribution of the lead content provided no additional knowledge as compared with surface sampling. Empirical semivariograms calculated on the basis of 2–16 pairs of original data sets were found which are better fitted by an exponential function than by a spherical model (as an example see Figure 9a). Because of the finely-dispersed

![Figure 9](image-url)
distribution of lead within the slag, a nugget variance was not observed. Theoretically the kriging procedure with a fitted spherical function provided additional data, on the basis of which a three-dimensional picture of the spatial variability was obtained (Figure 9b). But because of the small number of original data, the large distances between the neighboring sampling locations and the unavoidable errors of variograms and kriging, the validity and usefulness of the geostatistical conclusions were questionable.

Random Sampling Analysis. It was shown that the spatial variability of a chemical component of the slagheap cannot be successfully evaluated by geostatistical methods if this component is heterogeneously distributed over the heap. To avoid this, and to guarantee that the geostatistical assumptions (i.e. a homogeneous isotropic random field), are more likely to be fulfilled, the entire slagheap can be partitioned into several relatively small subregions. However, this procedure requires a more close-meshed sampling pattern to provide the data necessary for a reliable geostatistical evaluation.

If a detailed characterization of the slagheap is too expensive compared with the benefit expected, and the localization of highly contaminated subregions is impossible or unnecessary, the spatial location of any datum point obtained is not of interest. In such cases, random sampling analysis is recommended. Using random sampling analysis, the original data are assumed to be randomly located and stochastically independent. Independent variables are also uncorrelated. Then, the slagheap is globally evaluated by estimating the overall true content (expectation value) and the variance of the original data. The true content is estimated by the overall mean of all data available. The absolute difference between the mean and the (unknown) true value defines the absolute error (accuracy) of estimation. If an upper bound of this error and a lower bound of its confidence probability are prescribed, the minimum number of randomly located samples necessary to fulfill these limitations can be calculated.

For example, let $\mu$ be the true content of a component. Furthermore, let $\overline{Y}_n$ be the mean and $S_n^2$ be the empirical variance obtained by $n$ samples, respectively. $\overline{Y}_n$ and $S_n^2$ are random variables. Here and in the following, the random variables are represented as capital letters, and the corresponding actual values are written as lower-case letters. Hence $s_n^2$ is the actual value of the empirical variance $S_n^2$, and $\overline{y}_n$ is the actual value of the mean $\overline{Y}_n$. The true content $\mu$ is not known, as a rule, but it can be replaced by the mean $\overline{Y}_n$. In doing so, an error is made. The difference between the mean and the true value is called the absolute error of estimation or the accuracy of prediction, and this error is denoted as $|\overline{Y}_n - \mu|$. This error is a random variable with an expected value of zero and a standard deviation $S_n/\sqrt{n}$. As the standard deviation $S_n$ is the mean error of any individual observation, the quantity $S_n/\sqrt{n}$ is the mean error of the mean $\overline{Y}_n$. The mean error of the mean is abbreviated as $S_n$. A random interval which covers $\mu$ at the confidence probability (confidence level) $b$ is defined by Equation (20).

$$\overline{Y}_n - S_n \sqrt{\frac{1}{n}} < \mu < \overline{Y}_n + S_n \sqrt{\frac{1}{n}}$$

Here, $t_{n-1;1(1+b)/2}$ is the quantile of the order $(1+b)/2$ of the Student’s $t$-distribution at the degree of freedom $n-1$; this value can be found in tables of mathematical statistics.4 Furthermore, by rearranging Equation (20), an upper bound of the absolute error of estimation $|\overline{Y}_n - \mu|$ at the confidence probability $b$ is obtained (Equation 21).

$$e_n = \frac{S_n}{\sqrt{n}} t_{n-1;1(1+b)/2}$$

The quantity $e_n$ is called the probable error of estimation of $\mu$ by $\overline{Y}_n$ at the confidence probability $b$. The confidence probability $b$ is taken to be 90–95%, as mentioned above. In practice, an upper bound of the probable error of estimation, say $e_0$, at a certain probability $b$ is prescribed. That is, a quantity $e_0$ is required which fulfills the condition $|\overline{Y}_n - \mu| \leq e_0$ at the probability $b$. This bound is called the maximally admissible error of estimation. Substituting $e_n$ for $e_0$ and $n_0$ for $n$ in Equation (21), the inequality shown in Equation (22) is obtained.

$$e_0 \leq \frac{S_{n_0}}{\sqrt{n_0}} t_{n_0-1;1(1+b)/2}$$

If an estimated value $s_n$ of $S_{n_0}$ is known, and if for $t_{n-1;1(1+b)/2}$ an approximate value of 2.00 at confidence probability 95% is taken, the minimum number of samples $n_0$ necessary to fulfill the condition in Equation (22) is obtained according to Equation (23).

$$n_0 \geq \frac{4 s_n^2}{e_0^2}$$

For the special case where the admissible error of the mean must not be greater than the mean error of any individual observation ($e_0 = s_n$), at least $n = 4$ samples are needed. To be sure that this requirement is fulfilled even with one outlier, five samples are taken in practice. If the stronger condition $e_0 = s_n/2$ is required, $n = 16$ samples are needed. The procedure explained above was applied to globally evaluate the lead content of the slagheap. A number $n = 54$ of surface samples were considered. The mean value $\overline{y}_n = 0.98\%$, the empirical variance $s_n^2 = 0.18\%^2$ (see Equation 7) and the standard deviation $s_n = 0.42\%$
were calculated. The two-sided quantile of the Student’s $t$-distribution with a degree of freedom $n - 1 = 53$ at a confidence level of 95% is $t_{53, 0.975} = 2.0057$. A quantile of a distribution function at the confidence level $\beta$ is called two-sided or two-tailed if the relation $t_{(1-\beta)/2} = t_{(1+\beta)/2}$ holds. This is fulfilled when the distribution is symmetrical to the expectation value zero. By putting the $t$-value, the actual mean $\tilde{y}_n = 0.98\%$ and the empirical variance $s_n^2 = 0.18\%^2$ into Equation (20), the interval (0.86%, 1.10%) was calculated. This interval covered the true lead content at a probability of 95%. This estimate corresponds to an accuracy of prediction of $\varepsilon_n = 0.12\%$. When $\varepsilon_0 = 0.10\%$, $n_0 \geq 4 \times (0.18/0.01) = 72$ samples are needed. To guarantee this accuracy, the 56 surface sampling points and one sample from each of the 18 percussion coring wells would have been sufficient if the standard deviation $s_n$ had not been changed considerably.

If the situation allows gradual sampling, chemical analysis and statistical evaluation of the data the number of samples needed for a prescribed precision of estimating $\varepsilon_n$ at a given confidence probability $\beta$ can be sequentially determined in the following way. Let $n$ be the minimum number of samples available at the beginning of the investigation, say $n = 5$ as an example. Then, the mean $\tilde{y}_n$, the error of the mean $s_{\tilde{y}_n}$ and the probable error of estimation $\varepsilon_n$ are calculated. If $\varepsilon_n < \varepsilon_0$ holds for a prescribed $\varepsilon_0$ at a given confidence probability $\beta$, the investigation is finished. If it is not, additional samples are taken, the statistical parameters $\tilde{y}_n$ and $s_{\tilde{y}_n}$ are calculated and the actual probable error of estimation, $\varepsilon_n$, is compared with the given maximum admissible error of estimation $\varepsilon_0$. The investigation is continued until the condition $\varepsilon_n < \varepsilon_0$ with the actual number of samples $n$ is fulfilled.

Figure 10 shows a graphical presentation of the mean lead content $\tilde{y}_n$ and the lower and upper confidence limits $\tilde{y}_n \pm \varepsilon_n$ for the true content $\mu$ at a confidence probability 95% against the number of samples $n$. The influence of possible outliers and extreme values on the estimation process obviously decreases as the number of samples increases, as expected.

Finally, let us compare the benefit of a random sampling method with a systematic method. As mentioned above, the error of the mean $s_{\tilde{y}_n}$ measures the efficiency of a sampling method. In contrast to random sampling analysis, the systematic method takes into account the allocation of the data in space. For a data series consisting of $n$ subsequently allocated data points, the squared error of the mean is calculated according to Equation (24).

$$ S_{\tilde{y}_n}^2 = \frac{S_Y^2}{n} + 2 \sum_{\tau=1}^{n-1} (n-\tau)K(\tau) $$

In this equation, besides the quantities explained above, $K(\tau)$ is the value of the correlation function $K$ describing the degree of correlation (correlation coefficient) of each of two measuring variables observed at a spatial distance of $\tau$ from each other.

Obviously, the error of the mean increases as the correlation coefficient between the variables at different sampling locations increases. The correlation function $K$ is immediately related to the semivariogram function $\gamma$ or the variogram function $V$. Because of Equation (4), and $S_Y^2 = C_Y(0)$, the value of the semivariogram function at the lag $\tau$ is expressed as shown in Equation (25).

$$ \gamma(\tau) = S_X^2 \left[ 1 - \frac{C_X(\tau)}{S_X^2} \right] $$

Here, $C_X(\tau)/S_X^2$ is the value of the correlation function $K$ mentioned, and this quantity is abbreviated as $K(\tau)$. Equation (26) thus results from Equation (25) as follows.

$$ K(\tau) = 1 - \frac{\gamma(\tau)}{S_Y^2} $$

Substitution of Equation (26) for $K(\tau)$ in Equation (24) gives Equation (27).

$$ S_{\tilde{y}_n}^2 = \frac{S_Y^2}{n} + 2 \sum_{\tau=1}^{n-1} (n-\tau) \left[ 1 - \frac{\gamma(\tau)}{S_Y^2} \right] $$

This equation emphasizes the connections between random sampling analysis and geostatistical analysis. In practice, the mostly unknown variance $S_Y^2$ in Equations (24) and (27) is replaced by the respective estimate $S_{\tilde{y}_n}^2$ obtained according to Equation (7). In the special case of no correlations at any lag ($K(\tau) \equiv 0$ for any $\tau$), the semivariogram function $\gamma$ already has its maximum, actually $S_Y^2$, at the minimal lag $\tau = 1$. Substituting $S_Y^2$ for $\gamma(\tau)$ at any lag $\tau$ in Equation (27), and considering that $\sum_{\tau=1}^{n-1} (n-\tau) = n(n-1)/2$, the expression ...
\[ S^2_{Y_n} = S^2_Y/n \]
describing the squared error of the mean of \( n \) randomly chosen variables results from Equation (27). This error is lower than any other error calculated by Equation (27) on the basis of the same number of correlated data. Thus, time-consuming and costly geostatistical planning and sampling experiments to investigate extremely heterogeneous heaps and wastes is justified only for compelling reasons, for example if there is a particularly great interest in evaluating the spatial variability of certain regions. Otherwise, random sampling analysis is preferred. In the case of the Saxon slagheap, a sampling distance in the same order of magnitude as the range (correlation length) should be chosen.

### 3.1.5 Summary and Conclusions

In some cases sampling according to a systematic pattern followed by geostatistical evaluation can be successfully used to obtain a realistic picture of the spatial variability of the slagheap. Empirical (semi)variogram functions were calculated using original data in definite directions of the field of investigation and in fixed levels of the heap. The empirical variogram functions were fitted by a spherical model. Nugget effect, sill and range were easily interpretable parameters of this model. The technique of point kriging was applied to calculate data for additional points on the basis of the fitted variogram functions. Using the original data and the calculated values, three-dimensional presentations show the spatial variability of essential chemical components such as iron, zinc and lead. Useful results were obtained for the sulfur content in all directions and all levels. The geostatistical evaluation of the iron content only provided valuable variograms and kriging data in some directions of the heap. However, the iron content varied so widely in other directions that geostatistical methods did not work there either. The cadmium and the arsenic contents were untypical of the composition of the slagheap. The semivariograms calculated were either difficult or impossible to evaluate and showed neither preferred directions of variability nor any geostatistical regularity.

To sum up, it can be concluded that the highly expensive sampling, chemical analysis and geostatistical evaluation of extremely heterogeneous heaps of slags and industrial wastes are justified only by compelling reasons. However, reasonable results are obtained even with the wrong assumptions, because many geostatistical procedures are fairly robust. On the other hand, sampling regulations based on relationships between grain size and sample mass fail for contaminated sites and wastes where the structure has been markedly changed by physical and chemical processes, such as leaching, carbonization at low temperatures, precipitation, etc. If a global evaluation of the heap by mean values and variances of certain chemical components has priority, however, the usual methods of sampling and statistical data analysis recommended and developed for bulk materials and soils are promising tools.

The methodical results obtained from evaluating extremely heterogeneous contaminated sites and wastes in the Saxon slagheap example clearly show the possibilities and limitations of known sampling methods and geostatistical models. On the one hand, probably the greatest disadvantage in applying geostatistics is the difficulty in knowing whether the assumptions, for example a homogeneous isotropic random field, are acceptable or not in an individual case. On the other hand, such a close-meshed sampling and percussion coring pattern as applied in the case of the Saxon slag heap cannot be realized under commercial conditions. In practice, a compromise must be made. A promising strategy is to lay a regular grid over the region so that the coordinate origin and axis orientation are random. Then, samples are taken either systematically at each grid point or randomly at each subsection of the pattern. As shown in the example of the slagheap, one advantage of systematic sampling using a randomly placed grid is that the data obtained are very suitable for analysis by random sampling and geostatistical methods.

### 3.2 Evaluation of a Mercury-contaminated Site – A Problem of Sampling and Sample Pretreatment

#### 3.2.1 Introduction

To make decisions concerning contaminated sites, a reliable estimation of the environmental risk caused by hazardous components is necessary. This estimation can be performed by means of soil analysis, for instance. In this case, errors resulting from sampling, sample preparation and chemical analysis are unavoidable. To restrict these errors and to achieve comparable and legally valid criteria for the pollution levels, certain regulations must be considered.\(^{(52)}\) Until recently such regulations have been available only for limited fields of application. The rules commonly used for the evaluation of contaminated sites were originally developed for soils, water, sewage and sludges. The DEV are methods relating to the investigation of water, sewage and sludges\(^{(34)}\) and to sewage sludge regulation.\(^{(52)}\) A detailed overview of the German, European and International standards used for the determination of physical properties and the composition of inorganic pollutants in soils is given in Tables 5, 6 and 7.\(^{(53)}\)

To apply these rules in soil quality estimation, it is assumed that:

1. the soil is in an area (potentially) suitable for agricultural or horticultural use;

2. the inorganic contaminants in particular are distributed relatively uniformly over the whole area investigated;
3. the concentrations are low and of the same order of magnitude as the geologically originated background containing mainly nonvolatile compounds.

In contrast, the hazardous components of contaminated sites can occur in high concentrations, be distributed nonuniformly over the area of investigation and be bound in analytically relevant amounts to volatile species. If there is improper handling of the soil samples after sampling, chemical analysis can result in concentrations that are too small. This problem is known and can be controlled by regulations existing for sample preparation and for analysis of volatile compounds such as halogenated hydrocarbons, chlorinated hydrocarbons, hydrocarbons and phenols.

The fact that heavy metals such as mercury can escape from the soil sample is so far not reflected in the regulations for sample preparation. Mercury is known to exist in several forms or species in the environment. For the evaluation of contaminated sites, volatile species are of special interest.

1. All kinds of volatile mercury species such as elemental metallic Hg(0), methylmercury, dimethylmercury and phenylmercury, could be emitted by anthropogenic sources.
2. Bacteria are able to transform Hg²⁺ into volatile methylmercury. This process is described for various environmental matrices and conditions. Bacteria are also able to reduce Hg²⁺ to volatile Hg(0). In such cases, a high vapour pressure of metallic mercury is responsible for its volatilization as the soil sample dries up.
3. Methylmercury can be transformed into volatile Hg(0), methane and other organic compounds by microbial activity and by abiotic processes.
4. Hg²⁺ can be transformed into Hg(0) by abiotic reduction.
5. In addition, mercury and its species adsorb to different types of materials (e.g. plastic bags for soil samples), and are released in an uncontrollable manner.

The aim of our investigations was to find out, using an example, to what extent the analytically detectable mercury content of soil samples taken from contaminated sites is influenced by the handling of samples between sampling and sample preparation. Handling covers all the means by which the soil sample can be exposed, up to its preparation for chemical analysis. These procedures are termed sample pretreatment in order to distinguish them from sample preparation by homogenization, splitting and reduction. Thus, methods of storing the sample material under different natural conditions or even active procedures that change the physical or chemical structure of the sample material (such as thermal evaporation at different temperatures) also define sample pretreatment measures. However, the measured results can be influenced not only by sample pretreatment but...
also by errors of sampling, sample preparation and chemical analysis. Finally, we must take into account the fact that, in practice, the measured mercury content should reflect the intrinsic properties of the soil sample. These properties depend on the sampling location and are subject to global and local variations. To obtain general statements, it was necessary to plan the investigation program such that the different possible causes for the variation in measuring results could be evaluated independently. Other chemical components besides mercury were not investigated.

3.2.2 Object Investigated, Experimental Design

An industrial mercury-contaminated site was chosen as an example. Three locations of the site were investigated, named as A, B and C. At each point, primary samples of about 2 kg were taken from depths of 0–10 cm and 10–25 cm, respectively. Each primary sample was homogenized and split into three subsamples. The subsamples were separated again, and each portion was submitted to different pretreatment conditions before chemical analysis. The material obtained is referred to as a pretreated sample. The pretreatment methods were:

1. unchanged original material;
2. air drying for 2–4 weeks;
3. storing in a plastic bag for 2–4 weeks; and
4. thermal evaporation at 40, 60, 80, 105 and 120 °C.

For air drying for 2–4 weeks, about 100 g of the wet soil samples were spread on porcelain plates in a mercury-free atmosphere in normal light and at room temperature (20 °C).

For storing in plastic bags for 2–4 weeks, about 100 g of the wet soil samples were placed into commercial plastic bags and stored in a mercury-poor atmosphere in normal light and at room temperature (20 °C).

For thermal evaporation at 40, 60, 80, 105 and 120 °C about 20 g of the wet soil samples were placed in porcelain pans. The pans were placed on a sand bath at the chosen temperature for 24 h in a mercury-poor atmosphere. The mercury content of the laboratory atmosphere was determined once a week and proved to be below 80 ng m⁻³.

Two or three final samples of 3 g each were selected from each pretreated sample and digested by 10 ml HNO₃/HCl (Merck) for 4 h at 90 °C according to DIN 38414-7 (see Tables 6 and 7). All chemicals were of analytical grade. Water from a Milli-Q purification system was used throughout. A 20% m/V solution of tin(II) chloride in 15% HCl (Merck) was applied in the reduction step. The calibration was carried out using mercury(II) solution (Merck). A Perkin-Elmer (model 430) atomic absorption spectrometer, equipped with a MHS 20 mercury hydride system with amalgam attachment and a model 056 recorder (Spectraphysics) were used for the total mercury determinations.

The measuring results can be arranged in a hierarchical scheme as shown in Figure 11.

The total amount of samples from a sampling location is referred to as the gross sample. If the mean values are formed to each branch of a hierarchical level in the scheme shown in Figure 11, for a gross sample, a primary sample within a gross sample, a subsample within a primary sample, etc., the following questions arise.

1. Are the mean values of the gross samples significantly different from each other, i.e. does the sampling location significantly influence the mercury content?
2. Are the mean values of the primary samples of a particular gross sample significantly different from each other, i.e. does the sampling depth influence the results at a sampling location?
3. Are the mean values of the subsamples from one primary sample significantly different from each other, i.e. is sample preparation a statistically important source of error?
4. Given that pretreated samples from one subsample produce significantly different results, does the method of sample pretreatment influence the mercury content detected by chemical analysis?

The first question is easily answered: the means of the three sampling locations are significantly different, as the frequency distribution of the mercury content clearly shows (see Figure 12).

3.2.3 Statistical Analysis of Data

3.2.3.1 Variance Analysis

The questions mentioned above are mathematically and statistically treated by a model of variance analysis of four-way hierarchical classification (because of the four classes of hierarchically ordered test conditions) with random effects (because the experimental conditions are chosen at random from a large number of possibilities) and with a balanced experimental design (each experimental condition of a certain hierarchical level is combined with the same number of experimental conditions of other hierarchical levels in every case). The principle of variance analysis is to reduce the comparison of mean values to the comparison of variances. These variances are obtained by splitting the total variance of the measured results into individual portions produced independently of each other by differences between sampling locations (global variations), between sampling depths of a sampling location (local heterogeneities), and by errors made in sample preparation, sample handling and chemical analysis. The following mathematical model can be given.
Two measured values were obtained for each pretreated sample. Let $Y_{ijklm}$ be the $m$th measured value belonging to the $l$th pretreated sample of the $k$th subsample from the $j$th primary sample at the $i$th sampling location. $Y_{ijklm}$ is thought to be decomposable as shown in Equation (28)

$$Y_{ijklm} = \mu + \alpha_i + \beta_{ij} + \gamma_{ijk} + \delta_{ijkl} + Z_{ijklm} \quad (28)$$

with $i = 1, 2; j = 1, 2; k = 1, 2, 3; l = 1, \ldots 10; m = 1, 2$. $\mu$ is the overall expected value, estimated from the mean of all measuring results; $\alpha_i$ is the random effect caused by global fluctuations of the mercury content within the contaminated site, measured by the difference between the mean obtained from the values at the $i$th sampling location and the overall expected value; $\beta_{ij}$ is the random effect caused by local heterogeneities of the contaminated site, described by the deviation between the $i$th gross sample mean and the respective $j$th primary sample mean, and is a measure of the random error of sampling; $\gamma_{ijk}$ is the random effect of sample preparation, which describes the random deviation between the mean of the $j$th primary sample at the $i$th sampling location and the mean of the respective $k$th subsample obtained by homogenization and splitting of the material of the primary sample; $\delta_{ijkl}$ is the random effect of sample pretreatment, measured by the deviation between the mean of the $l$th pretreated sample and the mean of the corresponding $k$th subsample from which the pretreated material was separated; and $Z_{ijklm}$ is the random error of analysis, which defines the deviation between the measured value $Y_{ijklm}$ and the respective mean of the $ijklth$ pretreated sample.

The following assumptions are made: that the measured values $Y_{ijklm}$ are normally distributed random variables with an expected value $\mu$ and a total variance $\sigma^2_{\text{total}}$, and that the effects $\alpha_i$, $\beta_{ij}$, $\gamma_{ijk}$, $\delta_{ijkl}$ and the measuring error
$Z_{ijklm}$ are normally distributed, mutually independent random variables with the expected value zero and respective variances $\sigma_i^2$, $\sigma_j^2$, $\sigma_k^2$, $\sigma_l^2$, and $\sigma_m^2$ for all $i$, $j$, $k$, $l$, and $m$. Then, the total variance can be expressed as the sum of these individual variances as shown in Equation (29).

$$\sigma_{\text{total}}^2 = \sigma_i^2 + \sigma_j^2 + \sigma_k^2 + \sigma_l^2 + \sigma_m^2$$

The components in Equation (29) are the variance components. The following designations are used: $\sigma_i^2 = \sigma_{\text{global}}^2$, $\sigma_j^2 = \sigma_{\text{local}}^2$, $\sigma_k^2 = \sigma_{\text{preparation}}^2$, $\sigma_l^2 = \sigma_{\text{pretreatment}}^2$, and $\sigma_m^2 = \sigma_{\text{analysis}}^2$. The quantity $\sigma_{\text{global}}^2$ represents the variance caused by global fluctuations of the mercury content over the site; $\sigma_{\text{local}}^2$ designates the variance by local heterogeneities and corresponds with the sampling error variance, in principle; $\sigma_{\text{preparation}}^2$ indicates particularly the variability between the mercury content of different subsamples obtained by homogenization and splitting of a primary sample; $\sigma_{\text{pretreatment}}^2$ describes the variance of the mercury content caused by the different methods of handling the subsamples before chemical analysis; and finally $\sigma_{\text{analysis}}^2$ is the variance of the error of chemical analysis.

The questions mentioned above regarding the influence of sampling conditions and handling of samples on the mercury content detectable by chemical analysis are reduced to significance tests of the respective variances. The statistical treatment of these questions can be done using analysis of variance (ANOVA). The following results were obtained.

1. The global fluctuations between the sampling locations of the contaminated site are highly significant. The variance $\sigma_{\text{global}}^2$ contributes about 88% to the total variance of the mercury content.
2. The local heterogeneity also significantly influences the mercury content, and its variance $\sigma_{\text{local}}^2$ amounts to 6% of the total variance. That is, the mean content at a location essentially depends on the depth from which the soil sample is taken. Generally, the mercury content near the soil surface is lower than that from deeper levels. This may be due to microbiotic changes of nonvolatile compounds into volatile species such as elemental metallic mercury, phenylmercury, methylmercury and others, and the leaching of soluble mercury salts.
3. The sample preparation variance $\sigma_{\text{preparation}}^2$ is non-significant. That is, the primary samples were split into statistically equivalent subsamples.
4. The sample pretreatment variance $\sigma_{\text{pretreatment}}^2$ is highly significant and of the same order of magnitude as the local heterogeneity variance. The error of sample pretreatment is three to five times greater than the error of the chemical analysis at a confidence probability of 95%. The chemical analysis variance $\sigma_{\text{analysis}}^2$ contributes less than 0.5% to the total variance.

3.2.3.2 Systematic Error of Pretreatment

Variance analysis was used to qualitatively prove that handling of the soil samples significantly influences the mercury content detectable by chemical analysis. To decide quantitatively to what extent the mercury content of the original material is changed by a particular method of sample pretreatment, further statistical comparisons were carried out. More precisely, it was necessary to assess the error made if pretreated samples are used instead of the original material. Additionally, the probability of this error was evaluated. To find out the appropriate test procedure, the statistical properties of the mercury content were checked. Since the mercury content was normally distributed, pairwise comparisons of mean values seems to be reasonable. Because there was no significant error of sample preparation, the subsample variances of the measured values obtained for a fixed pretreatment method were summed up to the respective pretreated sample variance. As shown by Bartlett’s test and Fisher’s $F$-test, the variances of different pretreated samples were proved to be statistically identical. That enabled us to use the two-sample $t$-test to compare the mean values obtained carrying out a fixed pretreatment method, with the respective mean of the unchanged original material of a primary sample. The comparisons were based on the following ideas.

First, the pretreatment methods were arranged in a certain order to formally designate them by symbols or numbers. Now, let $\mu_1$ be the true mercury content at a definite location and a definite sampling depth of the contaminated site, and $\mu_i$ the expected content after the $i$th method of pretreatment was applied to the original sample material ($i = 2, 3, \ldots$). The difference $|\mu_1 - \mu_i|$ is the systematic error which is made if the original material is not known and only the $i$th pretreated sample is available. Normally this error is not detectable, but the corresponding mean values $\bar{y}_1$ and $\bar{y}_i$ as well as the empirical variances $\bar{s}_1^2$ and $\bar{s}_i^2$ obtained by $n_1$ and $n_i$ independent samples, respectively, are known. The quantities $\bar{y}_1$, $\bar{y}_i$, $\bar{s}_1^2$, and $\bar{s}_i^2$ are realizations of the respective random variables $\bar{Y}_1$, $\bar{Y}_i$, $\bar{S}_1^2$, and $\bar{S}_i^2$. Using them, a random interval can be given which covers the systematic error $|\mu_1 - \mu_i|$ at a prescribed confidence probability $\beta$ (Equation 30).

$$I_\beta = [\bar{Y}_1 - \bar{Y}_i] \pm S \left[ (\bar{Y}_1 - \bar{Y}_i) \right] t_{m(1+\beta)/2}$$

Here, $t_{m(1+\beta)/2}$ is the corresponding quantile of Student’s $t$-distribution at the degree of freedom $m = n_1 + n_i - 2$. 
and (as shown in Equation 31)

$$S(\bar{Y}_1 - \bar{Y}_i) = \frac{(n_1 + n_i)(n_1 - 1)S_1^2 + (n_2 - 1)S_i^2}{n_1 n_2 (n_1 + n_2 - 2)}$$

(31)

is the standard deviation (the mean error) of the mean value difference $|\bar{Y}_1 - \bar{Y}_i|$. The length $|I_\beta|$ of the interval $I_\beta$ is termed the probable systematic error at the confidence probability $\beta$. Equation (32)

$$\epsilon_\beta = \frac{|I_\beta|}{\mu_1}$$

(32)

is the corresponding probable relative systematic error. This criterion seems to be well suited to illustrate the change of the expected mercury content of a soil material after handling by the $i$th pretreatment method. Since the content of the original material $\mu_1$ is mostly unknown, it must be replaced by an appropriate estimation such as the lower limit $\mu_{1,\beta}$ of the confidence interval for $\mu_1$ at the confidence probability $\beta$ obtained as shown in Equation (33)

$$\mu_{1,\beta} = \bar{Y}_1 - t_{n_1 - 1,\beta/2} \frac{S_1}{\sqrt{n_1}}$$

(33)

where $t_{n_1 - 1,\beta/2}$ is the quantile of Student’s $t$-distribution at the degree of freedom $n_1 - 1$. The systematic error $\epsilon_\beta$ in Equation (32) is dimensionless and may be also given as a percentage.

Figure 13 compares the probable relative systematic errors caused by storing the sample in a plastic bag for 2–4 weeks, for samples from locations A and B at a sampling depth of 0–10 cm. A probable relative systematic error up to 40% may occur at a confidence probability of 95%. Storage of the soil samples in plastic bags for 2–4 weeks had the same effect as thermal evaporation at 40°C. Generally, the absolute loss of mercury in a soil sample depends only on the method of handling and not on the original concentration or the sampling location. Therefore, the lower the original concentration, the greater the relative systematic error. Furthermore, this error increases as the confidence probability increases. Thus, the accuracy in determining the influence of sample pretreatment on the mercury content detectable by chemical analysis at a given probability, and under fixed conditions of sampling and analysis, can be improved by decreasing the mean error of the mean value difference $S(\bar{Y}_1 - \bar{Y}_i)$ in Equation (31). This can be done by increasing the degree of homogenization of the samples and by increasing the numbers of samples, $n_1$ and $n_i$. Interlaboratory tests and intralaboratory tests must be done to improve the repeatability and the reproducibility of the instrumental measurements. (59)

To qualify the results represented, it must be emphasized that the definite errors mentioned are valid only for the object investigated and must not be immediately transferred to any other contaminated site. However, they may serve as a basis for developing regulations for the handling of soil samples contaminated by volatile compounds and for introducing instruments to control the influence of the handling on the mercury content detectable by chemical analysis.

### 3.2.4 Summary and Conclusions

Using the example of a mercury-contaminated site, it was demonstrated that the handling of soil samples can affect the mercury content detectable by chemical analysis. To distinguish this effect from the errors of sampling, sample preparation and chemical analysis, as well as from the local environments of the geogenic background, the following sampling design was used. One soil sample (called the primary sample) was taken at two different depth intervals from each of three locations, and each primary sample was then split into three more portions, called subsamples. The subsamples were again separated into several parts, each of which was submitted to a particular method of handling before analysis. Every method of handling defines a method of sample pretreatment. One portion was kept as the unchanged original material, and its mercury content was immediately determined. The following methods of sample pretreatment were applied: air drying for 2–4 weeks; storing in plastic bags for 2–4 weeks; and thermal evaporation at different temperatures from 40°C up to 120°C. The pretreated samples were analyzed, and the mercury content detected was compared with the content of the respective original material.
First, variance analysis was applied to globally quantify by variances the effects of sample pretreatment, sample preparation, global fluctuations, local heterogeneities and chemical analysis. The dominant source of variability was the global fluctuations of the mercury content. “Global fluctuations” means that the mercury content varies significantly from location to location. These fluctuations were caused by the geogenic structure of the soil. As it turned out, the variability caused by sample pretreatment was of the same order of magnitude as the local heterogeneity variance. The local heterogeneity variance corresponds to the sampling error variance. A significant error of sample preparation did not actually exist.

Second, the qualitative statement that sample pretreatment influenced the mercury content determined by laboratory measurement was quantified by the concept of the probable systematic error of pretreatment. Following this concept, the difference between the mean mercury content of the pretreated sample and the mean value of the respective original sample material describes the systematic error which is made if the original soil material is not available, but only material handled by a certain method can be investigated. For example, if storing the soil material in a plastic bag for at least two weeks, a probable relative systematic error of up to 40% at a confidence probability of 95% must be taken into account. The concrete results obtained cannot be immediately transferred to other objects, but they may serve as a basis for developing regulations for the handling of soil samples containing volatile compounds and for introducing controlling instruments.

**ACKNOWLEDGMENTS**

The geostatistical calculations reported here were carried out by M. Herbst using the Windows-based commercial computer program “Surfer”, which is frequently used for geostatistical applications. The author wishes to thank him for providing the calculations and for helpful discussions regarding the interpretation of the results.

The list of analytical chemistry methods used for the investigation of wastes was compiled by K. Volke. He also compiled the German, European, American and International standards for this field as well as for the determination of pollutants in soils and elutriates. The author wishes to thank him for his careful work and for some useful advice.

**LIST OF SYMBOLS**

- \( a \): Range, Correlation Length, Minimum Distance Between Uncorrelated Data
- \( b_t \): Parameter of a Linear Variogram Model Function
- \( C \): Partial Sill of a Variogram Model Function
- \( C_{er}, a_e \): Parameters of an Exponential Variogram Model Function
- \( \text{cov} \): Covariance Operator of Two Random Variables
- \( C_Y \): Covariance Function
- \( C_0 \): Nugget Effect Obtained by a Variogram Model Function
- \( D^2 \): Variance Operator of a Random Variable
- \( D^2 Y_t \): Variance of a Random Variable \( Y_t \)
- \( E \): Operator of the Mathematical Expectation of a Random Variable
- \( EY_t \): Expectation Value of the Measuring Variable \( Y_t \) at the Point \( t \)
- \( G \): Set of all Possible Points of the Slag Heap
- \( I_\beta \): Probable Systematic Error at the Confidence Probability \( \beta \)
- \( K \): Correlation Function
- \( m \): Degree of Freedom in Statistical Comparisons
- \( n, n_1, n_i \): Number of Samples
- \( S_n \): Standard Deviation of a Measuring Variable \( Y \), Mean Error of an Individual Value
- \( S^2_n, S^2_Y, S^2_1 \): Empirical Variance Obtained by \( n \) Samples, Maximum Variance of a Variable \( Y \), Sill
- \( S^2_{\tau_n} \): Variance of the Mean Obtained by \( n \) Samples
- \( S ((\bar{Y}_1 - \bar{Y}_i)) \): Standard Deviation of the Mean Value Difference \( |\bar{Y}_1 - \bar{Y}_i| \)
- \( t_{\text{mc}(1+\beta)/2} \): Quantile of the Order \( (1+\beta)/2 \) of the \( t \)-Distribution at the Degree of Freedom \( m \)
- \( t, t + \tau \): Points, Sampling Locations
- \( V \): Variogram Function
- \( V_{\text{total}} \): Total Variance
- \( w_i \): Weight of a Measuring Value at a Point \( t_i \)
- \( \bar{Y}_n \): Mean Value Obtained by \( n \) Samples
- \( |\bar{Y}_n - \mu| \): Absolute Error of the Mean \( \bar{Y}_n \)
- \( \bar{Y}(t_0) \): Mean of a Random Variable \( Y \) at the Point \( t_0 \)
- \( Y, Y_t \): Random Variable, Measured Variable at a Location \( t \)
- \( Z_{ijklm} \): Random Error of Analysis
- \( \alpha_i \): Random Effect of Global Fluctuations
- \( \beta \): Confidence Probability, Confidence Level
- \( \beta_{ij} \): Random Effect of Local Heterogeneities
- \( \alpha_i \): Random Effect of Local Heterogeneities Within a Model of Variance Analysis
- \( \beta \): Confidence Probability, Confidence Level
- \( \beta_{ij} \): Random Effect of Local Heterogeneities Within a Model of Variance Analysis

Infrared Spectroscopy in Environmental Analysis

Tom Visser
National Institute of Public Health and The Environment, Bilthoven, The Netherlands

1 Introduction

Infrared (IR) spectroscopy is a universal, versatile analytical technique for the structure elucidation and quantification of a large variety of organic, inorganic and biological samples. The technique is based on the measurement of IR radiation, absorbed or emitted by a sample, as a function of the wavelength in the region 2.5–100 μm, or 4000–100 cm⁻¹ in wavenumbers. The absorption or emission of IR radiation is related to discrete vibrational and rotational transitions in a molecule and, therefore, represents structural information. The analytical value of IR spectroscopy is based on the fact that the IR bands occur at more or less localized positions in the spectrum which are correlated to the presence of characteristic structural features of the sample under study. This similarity and transferability of spectral characteristics and the corresponding structural features, makes IR a powerful tool for functional group analysis. On the other hand, vibrations, and thus the exact peak positions, are sensitive to the local environment which also makes IR spectra unique molecular fingerprints, highly suited for the unambiguous identification of a sample by comparison with reference spectra. Finally, IR spectroscopy obeys Beer’s Law and can thus be used for quantitative purposes too.

The major advantage of IR over other spectroscopic techniques is that practically all compounds show absorption/emission and can thus be analyzed both quantitatively and qualitatively. Besides, IR spectroscopy is nondestructive and admits in situ and remote measurement of almost any sample, irrespective the physical state and without elaborate preparations. A broad variety of advanced accessories and technologies, such as IR microscopy, optical fibers, remote sensing, reflection and emission equipment and the combination with gas chromatography (GC), liquid chromatography (LC) and supercritical fluid chromatography (SFC) sampling and measurement techniques are available to tackle a diversity of problems. The absolute sensitivity is about 50–500 picograms, which is sufficient to solve many problems in trace analysis.

IR spectroscopy is used in a broad range of environmental applications. The technique is a viable tool in remote measurements of gases, liquids and solids and as a fast and reliable method for the characterization and indicative structure classification of a wide variety of samples. Besides, IR is widely applied for identification purposes either to confirm results of other techniques or for reasons of quality assurance (QA).

1 INTRODUCTION

The identification of molecular structures and the determination of their concentration in the sample is an essential part of environmental analysis. Among other selective techniques such as ultraviolet (UV), fluorescence, atomic emission and mass spectrometry, IR spectroscopy has gained wide acceptance as a viable technique for this purpose. The principle of IR spectroscopy is the measurement of the amount of IR radiation absorbed or emitted by a sample as a function of the wavelength. The wavelength of IR ranges from about 0.8 to 100 μm (12500–100 cm⁻¹ in wavenumbers) and is divided into a near-infrared (NIR) (12000–4000 cm⁻¹) and a mid-IR (mid-infrared) (4000–100 cm⁻¹) part. This
chapter deals with the spectroscopy related to the mid-IR radiation. NIR spectrometry is discussed in the article Liquid Chromatography/Infrared Spectroscopy in this encyclopedia.

The absorption or emission of IR photons is related to rotational and vibrational transitions in a molecule and therefore represents structural information. The corresponding IR bands occur at discrete frequencies in the IR spectrum and this relation between the molecular structure of a sample and the IR spectrum is the most important analytical value of IR spectroscopy.

The potential of IR spectroscopy in the elucidation of molecular structures is very high. The number of fundamental vibrations in a molecule of \( N \) free-moving atoms is \( 3N - 6 \). In principle, each vibration may give rise to an absorption or emission band but in practice the number is smaller as vibrations may be inactive as result of symmetry and degeneracy. On the other hand, much more than \( 3N - 6 \) absorption bands may be present in the spectra of vapor-phase molecules as result of rotational transitions. Besides, vibrations and rotations are sensitive to a number of physical parameters, such as temperature and pressure, and to intra- and intermolecular interactions. The large number of vibrations and rotations, and the diversity of variables affecting these, make IR spectra unique molecular fingerprints, highly suited for the identification of a sample by comparison with reference spectra.

Valuable structural information can also be derived from the interpretation of spectra, e.g. in case a matching reference spectrum is absent. Contrary to identification, based on the discriminative properties of the spectrum, interpretation relates to the similarity and transferability of spectral characteristics and the corresponding structural features of molecules, i.e. functional groups. For that reason IR spectroscopy is also a useful technique for the characterization and structural classification of samples. However, as result of the large number of variables affecting a spectrum, it is extremely difficult to arrive at a complete molecular structure from a single spectrum without additional knowledge.

Finally, IR spectroscopy is an absorption technique obeying Beer's Law. It can thus be used for quantitative purposes too. A drawback compared to, for instance, UV, visible and fluorescence spectrometry is the small extinction coefficient of IR absorption bands resulting in relatively poor detection limits. Nevertheless, the current absolute limit of detection of about 10–50 picograms, is sufficient to solve many problems in environmental trace analysis.

The major advantage of IR over other techniques is that, apart from homonuclear diatomic molecules such as \( \text{H}_2, \text{N}_2 \) and \( \text{O}_2 \), all compounds show IR absorbance and can thus be analyzed qualitatively as well as quantitatively. Besides, IR is a nondestructive, non-contact technique, offering the possibilities to perform in situ and remote measurements. From this practical point of view, IR is probably the most versatile of all analytical techniques, as a spectrum can be recorded of almost any sample, irrespective of the physical state and without elaborate preparations within tenths of a second. This versatility has made IR spectroscopy a valuable analytical tool in a variety of environmental applications.

## 2 HISTORY

Since the development of IR spectroscopy in the early 1940s the instrumentation and environmental applications have developed through a number of stages. The first generation IR spectrometers were single-beam instruments with alkali halide prisms as the dispersive element. The sensitivity and the resolution of these instruments were poor, limiting the applications to functional group analysis and indicative quantification of milligrams of material.

In the 1960s, the instruments became double-beam, and Echelette gratings, combined with optical filters for order separation, replaced the prisms. As a consequence, the optical resolution and the stability and sensitivity of IR spectrometers were considerably enhanced and the detection limits extended to micrograms. A further development, the coupling to chromatographic techniques, via stopped-flow and flow-through cells, led to new applications, particularly in the structure elucidation of constituents in complex matrices.

A further positive impulse was given by the incorporation of computers into the IR spectrometers. Advanced data acquisition and manipulation techniques such as spectrum subtraction, programmes to search in large libraries of digitized spectra, and chemometrical methods were brought to the bench of IR spectroscopists.

Finally, the introduction of the Fourier transform (FT) principle in IR spectrometers in the 1970s dramatically improved the possibilities of IR spectrometry in a wide range of analytical problems. The high scanning speed and sensitivity of Fourier transform/infrared (FT/IR), combined with extended computer facilities for data manipulation and the development of a series of advanced accessories and technologies, such as IR microscopy, high resolution interferometers (\( > 0.001 \text{ cm}^{-1} \)), tunable lasers, specific detectors, reflection and emission equipment and the construction of mobile and portable instruments, have brought IR to its current state of versatility and popularity.
3 SAMPLING AND MEASUREMENT TECHNIQUES

As result of the unique versatility of IR spectrometry a broad variety of sampling and measurement techniques are available to tackle a diversity of problems. The development of several of these methods originate from an environmental demand. An illustrative example is the IR remote sensing technique for the qualitative and quantitative in situ determination of gases. The need to study emissions and chemical processes of greenhouse gases largely contributed to the development of this open-path technique to its current state of maturity. Obviously, the fact that global warming is assumed to be caused by the increasing release of exogenic IR-absorbing gases into the atmosphere, plays a role in this.

The principle of IR remote sensing is shown in Figure 1. In the passive mode, the sun is used as a light source or the spectrometer is operated as a detector to determine the IR radiation emitted by the subject of study. In the active mode the instrument operates as a classical source–detector spectrometer, recording absorption along the beam path to a flat mirror or a retroreflector and back. The IR source and the detector are either incorporated in one instrument or separated into modules.

Absorption measurement in a closed gas cell is a good alternative to carry out model studies and in case the analysis has to be performed on previously collected samples. Internal multi-reflection options offer the possibility of enlarging the effective pathlength to 1–100 m within the relatively small dimensions of a 10–30 cm gas cell. This method is particularly attractive in case extremely low detection limits are not crucial. Gas cells are used both separately as an accessory, and fixed, incorporated into a (mobile) spectrometer. An example of the latter is the commercially available mobile FT/IR spectrometer GASMET™ (Temat Instruments Ltd, Finland) as shown in Figure 2.

Remote measurements of gases, liquids and solids can also be carried out with the help of optical fibers. Fibers are used as a transmission wave guide to transfer the IR signal to and from a sensing probe, and as a sensing element itself. The fibers are made of materials such as chalcogenides that combine a certain physical flexibility with a high IR transparency. Optical fibers are particularly useful to carry out in situ measurements and to study compounds with possible toxic or corrosive activity. At present, distances of 5–50 m can be covered, depending on the desired wavenumber region to be scanned.

The advantages of optical fibers and solid-phase micro extraction (SPME) have been combined to a fiber optic

Figure 1 Schematic representation of the principle of active and passive remote sensing IR measurements.
sensor system for the analysis of microcontaminants in aqueous samples. The experimental set-up of this system is schematically depicted in Figure 3. The actual sensor consists of a silver halide fiber coated with a thin layer of polymer. Similar to SPME, the organic analytes are extracted from the water into the polymer film and scanned with a (portable) IR spectrometer after a certain equilibration time.

Conventional sampling methods such as the liquid cell and the KBr-pelleting technique, as well as more advanced methods such as diffuse reflectance infrared (DRIFT) and attenuated total reflection (ATR), are being used for the characterization and identification of samples in case the available amount is not the limiting factor. For quantitative purposes, liquid cells of variable pathlength, cell volume and window material are available.

IR microscopy is being employed for the analysis of small particles and in combination with the on- and off-line coupling to separation techniques for the determination of trace contaminants. The principle and applications of IR microscopy have been described by Messerschmidt and Harthcock. The application of IR microscopy as a detector in GC, LC and SFC has largely enhanced the sensitivity of these combined techniques. The current limit of detection is in the (sub)nanogram range which makes these hyphenated techniques useful alternatives or additives to commonly applied detectors such as flame ionization, electron-capture and mass spectrometry.

The interfacing of GC and IR is accomplished in three different ways which are all commercially available. The first one is on-line by means of a heated flow-through cell with an optical pathlength of 10–30 cm. This so called ‘light pipe’ interface allows continuous monitoring of the GC effluent.

The second one is off-line and comprises the trapping of the GC-separated analytes in an argon matrix on a rotating gold coated cylinder at 4K. After completion of the GC-run, the immobilized chromatogram can be scanned at any desired speed and resolution as long as the cryogenic conditions are maintained. This technique is called matrix isolation gas chromatography/infrared (GC/IR).

The third one is also a cryogenic sample storage technique and is called cryotrapping or direct deposition GC/IR. The analytes are crystallized directly on a moving IR transparent window at liquid nitrogen temperature (77K). Scanning can be carried out both on-line, a few seconds after deposition, or post-run, after completion of the GC separation.

The most important advantage of the sample storage methods is the sensitivity which is about two orders of magnitude better than that of a light-pipe instrument as result of the application of IR microscopy and the possibility of long-time signal averaging.

A series of papers on the environmental applications of GC/IR have been published by Gurka et al. The analytical value of multidimensional gas chromatography/infrared/mass spectrometry (GC/IR/MS) for the investigation of environmental samples has been summarized by Krock and Wilkins, while the synergetic value of GC/IR in combination with other spectrometric techniques has been reviewed by Ragunathan et al. IR detection in LC and SFC is accomplished on-line by passing the effluent through a liquid flow-through cell, or off-line by elimination of the solvent prior
to detection of the deposited analytes. Flow cells for any type of mobile phase, including supercritical fluids, and solvent elimination liquid chromatography/infrared (LC/IR) interfaces can be purchased from several companies. Off-line detection is highly favorable since important parts of the spectral region may be obscured by absorption bands of the eluents. Particularly in reversed phase, the strong absorption of water is a major limiting factor not only in terms of poor spectral information but also in sensitivity as a feasible pathlength should not exceed 10–20 microns. An extensive review of the merits and limitations of on- and off-line coupled LC/IR has been reviewed by Somsen et al.\(^\text{10}\)

### 4 ENVIRONMENTAL APPLICATIONS

Numerous papers on the application of IR spectrometry in environmental analysis have been published in analytical, environmental and spectroscopic journals. State-of-the-art surveys are frequently published of which the comprehensive biannual reviews of *Analytical Chemistry* on IR spectroscopy\(^\text{11}\) and environmental analysis\(^\text{12}\) are recommended as good starting points.

Papers on specific IR sampling and detection techniques also contain valuable information on environmental applications. Representative examples are the previously mentioned reviews on IR microscopy,\(^\text{5}\) GC/IR\(^\text{7–9}\) and LC/IR.\(^\text{10}\)

The diversity in applications is extremely large. The analytes vary from organic and bio-organic molecules to polymers, inorganics and even microorganisms. Next to air, soil and water, IR analysis is employed in all sorts of matrices at concentration levels between bulk and trace. Real-time and in situ measurements are performed for dynamic studies while various on- and off-line methods are being used for characterization, classification, structure elucidation and quantitative analysis. A summary of the IR spectroscopic applications is presented in Table 1. A selection of the most relevant and illustrative applications is described into more detail in the following sections.

#### 4.1 Indoor Air

The concern for good quality of indoor air has urged the development of techniques that are able to monitor the presence and release of harmful gases. Not only in the laboratory and industrial environment but also in, for instance cleaning and printing shops and during painting, relatively high concentrations of volatile organic compounds (VOCs) may be released. In principle, IR spectrometry is an attractive technique for the screening and monitoring of VOCs in the gas phase. All compounds show IR absorption and can thus be determined, while measurements can be performed remotely and continuously without any sampling. The sensitivity of IR is in the low ppm range, which is relatively low compared to some other techniques but sufficiently high for many applications. Therefore, several systems to monitor emissions of VOCs are based on IR detection.

Three types of IR–gas measurement systems can be distinguished:

1. low cost non-scanning detectors that are specifically used to determine the presence of one or two target-components;
2. portable instruments with filters or an interferometer for wavelength selection;\(^\text{2}\)
3. remote open-path IR spectrometers.\(^\text{13}\)

An instrument, specially designed to monitor indoor air concentrations, is the Infrared Gas Cloud (IGC) scanner developed by ter Kuile et al.\(^\text{14}\) This apparatus is used for the selective analysis of gases in the ppm range to visualize the spatial distribution of the analyte in the workplace. Specific applications are the testing of ventilation systems and the remote detection of gas leaks.

Dispersive IR analysis of gases, released by the smoking of cigarettes, proves to be a better method for quantification than most other spectrometric techniques. The yield for carbon monoxide, hydrogen cyanide and nitric oxide turns out to be about 45% higher when detected with IR.\(^\text{15}\)

In case direct IR measurement is hampered, for instance as result of weak absorbing properties of the analyte, indirect detection after conversion into a stronger absorbing compound is a good alternative. An example is the analysis of H\(_2\)S and O\(_2\) which can be detected at much lower concentrations after oxidation to SO\(_2\) and ozone respectively, by UV irradiation over a certain period of time.\(^\text{16}\)

Preconcentration techniques, occasionally combined with a derivatization or modification, are used as well. Fillipi\(^\text{17}\) for instance, developed a purge and trap method combined with a chemical reduction step prior to GC/IR and atomic absorption spectrometry (AAS) to determine methyl and dimethyl mercury in air at a 50 pg level.

#### 4.2 Atmosphere and Stratosphere

The detection of exogenic and endogenic gases in the outdoor atmosphere relies to a large extent on the same methods as used for the analysis of indoor air. Similar specific single-compound detectors are used for continuous monitoring or occasional field measurements to determine and quantify a selection of predefined harmful gases and VOCs at, for example, industrial

sites and waste incinerators. Multi-pass gas cells and open-path equipment are applied for the detection of other, non-target analytes.\(^{(18)}\)

Remote sensing open-path IR spectroscopy has substantial advantages over the other methods. It can be used to measure absorption as well as emission and the technique is capable of covering almost infinite distances. This offers the possibility of detecting fluxes of trace gases over a much wider area than can be achieved by any other technique. For that reason, active and passive remote sensing IR are the methods of choice for monitoring gases and gaseous emissions, not only in the lower atmosphere but at any altitude and even in space.

A review on atmospheric and stratospheric research is given by Farmer.\(^{(19)}\) Most studies focus on the detection and the quantification of a large variety of trace gases in order to monitor possible compositional changes as a result of human activities and to get insight into the underlying physical and chemical processes. Subjects of research are the fluxes and effects of fertilizers, pesticides, industrial waste contamination, energy production, etc. Analogous studies are performed on environmental burdening by compounds emitted from natural sources, such as plants, animals, volcanic activity and biomass burning. As noted before, special interest is given to the greenhouse effect and the depletion of the stratospheric ozone layer over the Arctic and Antarctic areas.

The IR spectra of gases in space and in the stratosphere exhibit extremely narrow vibrational and rotational bands as result of the very low temperature at site. In order to extract maximum information from the spectra, high-resolution facilities are essential and for that reason, measurements are preferably carried out with instruments with a data point resolution of 0.05 to 0.002 cm\(^{-1}\). As
well as molecules involved in the photodissociation of chlorofluorocarbons (CFCs), a diversity of other minor constituents such as CO, CH₄, HF, HCl, HCN, O₃, NO₂, NO, SF₆, N₂O, H₂O₂, OCS and ClONO₂ can be determined with this type of IR-spectrometric technique.

Measurements are performed:

1. directly by air-borne spectrometers in space and aircraft or in balloons;
2. directly by ground-based remote sensing techniques;
3. indirectly by laboratory analysis of samples collected by aircraft or balloon.

In addition to these techniques, kinetic laboratory studies are undertaken to mimic atmospheric and stratospheric conditions and processes. For this type of research, pressure- and temperature-controlled gas cells are used.

Air-borne instruments are in general of special design such as the Atmospheric Trace Molecule Spectroscopy (ATMOS) instrument that is used in Space Shuttle flights. Measurements from aircraft are usually preferred to observations from balloons, since the latter are relatively expensive and limited to balloon-accessible altitudes of about 45 km. Yet it is a viable and frequently used method for direct analysis and for the validation of data obtained from other techniques. Examples of ground-based measurements are the observations at the Jungfraujoch mountain station in the Swiss Alps, where IR spectra of the global atmosphere and stratosphere have been acquired over a period of almost five decades, and the measurements in the Arctic area where the column densities of several atmospheric gases have been determined during summer and winter seasons. In these observations, the sun is used as the IR light source, either directly at daytime or indirectly by reflection via the moon at night. Long-term scanning is required to get sufficient signal-to-noise ratio which implies that a tracker is necessary to follow the course of the emitting object. Examples of the information obtained from such high-resolution data are depicted in Figure 4 showing the extremely narrow absorption lines of HF and NO recorded at the Jungfraujoch observatory.

### 4.3 Smoke Stacks and Exhaust Gases

Many studies have been dedicated to the on- and off-line measurement of smoke stacks, and flue gases released from traffic and power plants. The popularity of the remote methods is rapidly growing due to the fact that it is a noncontact real-time technique. Besides, it enables the performance of multicomponent analysis in seconds.

A remote-sensing IR method to determine the constituents of the exhaust gas of a coal-fired power plant has been developed by E. Lindermeir. The principle of this method is the measurement of the emission lines of released gases at medium resolution (0.5 cm⁻¹). Accurate concentrations of H₂O, CO₂, CO, NO and SO₂ in smoke stacks at heights up to 200 m were calculated from the IR spectra using special algorithms to compensate for background fluctuations.

A commercial remote sensing FT/IR instrument RSD 1000, (Remote Sensing Technologies Inc. Maryland, USA) is used by Sjödin to determine the instantaneous concentrations of CO and hydrocarbons in the exhaust of motor cars. The measurements are used to select major polluters for subsequent roadside inspection. It has proven to be a useful tool to increase the efficiency of
roadside inspections to detect cars violating governmental idle test standards.

Roadside and laboratory inspections can be readily performed by flow-through and sampled gas cells as well. The portable mobile IR spectrometer GASMET™ for instance, equipped with a 1.8 m multipass gas cell, can detect a variety of exhaust gases at levels of 0.2–20 ppm.\(^{(2)}\)

Specific spectrometers have been developed for FT/IR emission measurements of aircraft engine exhausts under active conditions. It enables the determination of emission rates of gases like NO\(_x\), CO, CO\(_2\) and H\(_2\)O with a resolution of 0.2 cm\(^{-1}\) during the flight at cruising altitudes up to 25 000 ft.\(^{(26)}\)

A mobile air pollution search system has been developed by the Kayser–Threde Company (Munich, Germany). The system is based on a K300 double pendulum spectrometer that operates at a spectral resolution of 0.08 cm\(^{-1}\). In the passive emission mode, the instrument can determine gas concentrations of CO, CO\(_2\), N\(_2\)O, NO, SO\(_2\) and HCl in smoke-stack effluents of power plants and municipal incinerators with high accuracy.\(^{(27)}\)

### 4.4 Terpenes and Biogenic Aerosols

Environmental risk-assessment studies generally comprise the release of compounds of anthropogenic origin. From the viewpoint of health care, however, the emission of molecules from natural sources are of almost equal interest. The release of gases from a single volcanic eruption, for instance, can be in the order of billions of tons. Other sources that are known to have large impacts on the local or global environment are bush fires, aqueous microorganisms and emissions from terrestrial plants (terpenes) and animals (pheromones).

Terpenes, released from plants and trees, are known to be important in the formation of photochemical oxidants and secondary organic aerosols. To determine the qualitative and quantitative composition of terpene emissions and its oxidation products in the related aerosols, an IR spectroscopic method in addition to gas chromatography/mass spectrometry (GC/MS), has been developed by Schrader et al.\(^{(28)}\). It is demonstrated that cryotrapping GC/IR supplies important complementary information for the structure elucidation of mono- and sesquiterpenes as well as other ethereal compounds, at the high picogram level.

Biogenic aerosols from photooxidation of terpenes have been analyzed by Palen et al.\(^{(29)}\) too, using IR microscopy. The quantitative possibilities of this method are limited but valuable information can be obtained concerning the presence of compounds with oxygen-containing functional groups such as hydroxyls, ethers, ketones, aldehydes, carboxylic acids, lactones and esters.

Finally, IR spectrometry is also used to determine and characterize waterborne microorganisms in drinking water.\(^{(30)}\)

### 4.5 Volcanic Emissions

Passive and active open-path IR spectrometry are the principal methods of monitoring emissions from active volcanoes. The IR spectra are primarily used to determine the identity and flux of gases released during eruption. Other information that is extracted from the IR data deals with the eruptive history of volcanoes and the effects of vulcanism on the local and global climate. A case study on this subject is given by Chaffin et al.\(^{(31)}\). Measurements over pathlengths of 500 m to nearly 2 km have been carried out with a mobile spectrometer operating at a resolution of 0.5 cm\(^{-1}\). Large amounts of CO\(_2\) and SO\(_2\) in the volcanic plume hamper the identification of compounds that absorb in the same regions as these two components; however, several other constituents such as HCl, SO\(_2\) and SiF\(_4\) can be determined at ppm level in very short measurement times (less than one minute is typical). As an example of the performance of these measurements, the field-recorded spectrum of HCl and the vapor-phase reference spectrum of this compound, are depicted in Figure 5.

### 4.6 Biomass Burning

According to Griffith\(^{(32)}\) the burning of biomass is a highly underestimated source of air pollution. The annual release of carbon into the atmosphere as result of wild fires and the prescribed combustion of bush, forest, savanna and agricultural waste is about 3–6 gigaton which is of the same order as the annual combustion of fossil fuels. FT/IR studies are used to determine the composition of the smoke gases in order to distinguish between the different types of biomass burning and to assess the impact of this type of process on the atmosphere. The IR analysis is performed both directly by field measurements using long-open-path spectrometers, and by laboratory studies of smoke samples that have been taken by cold trapping in canisters at the ground and at higher altitudes using light aircraft. The in situ measurements are carried out at high resolution (0.05 cm\(^{-1}\)) with a typical pathlength of 20–200 m. The samples are analyzed by matrix isolation FT/IR.

Next to the well known carbon, sulfur and nitrogen oxides, tens of other trace gases including CS\(_2\), CSO, HCN, CH\(_3\)CN, and hydrocarbons have been identified and quantified. A spectrum, typical for a smoke sample, is shown in Figure 6.
4.7 Volatile Organic Compounds

The relevance of the determination of VOCs in the indoor and outdoor atmosphere, and the IR spectroscopic techniques that can be used for this purpose, have already been described in sections 4.1 and 4.2. Obviously, the analysis of VOCs in other matrices is of similar importance. A rapid screening method to determine and quantify VOCs in soil has been developed by Clapper et al. The principle of this method is the thermal desorption of the analytes from the soil sample with subsequent analysis of the vapor in a multipass gas cell.
with a pathlength of 13.2 m. The sensitivity is at microgram level.

Fiber-optic analysis is a useful alternative when direct analysis of high concentrations of organic solvents in soil is required. As shown by Ewing et al., this technique is very selective for the identification of benzene, toluene, ethylbenzenes and xylenes (BTEX) as well as for the remote detection of high concentrations of trichloroethylene.

Optical-fiber sensing is also used for the analysis of chlorinated hydrocarbons in water samples. The sensitivity of the sensor is increased by application of a polymer coating on the fiber surface. This type of analyte enrichment is analogous to the principle of SPME and enables the detection of chlorinated solvents such as tetrachloroethylene at a concentration level of 300 ppb.

SPME has also been used for direct detection of VOCs in water by extraction of the organic compounds into a 130 µm thick parafilm. After a certain equilibration time, the film is measured by IR transmission spectroscopy. Reproducible extraction and detection is achieved for VOCs such as benzene, toluene and chloro-toluene at concentration levels of 0.1–1 ppb.

Another technique for the determination of volatile pollutants in surface and wastewater is sparging-IR. This technique is based on the favorable partitioning of volatile and semivolatile organic molecules for the vapor phase over the liquid aqueous phase. Contaminants are forced into the vapor phase by a stream of nitrogen bubbles passing through the sample. Subsequently, the vapor is directed into a multipass gas cell for measurement of the target components. Sparging-IR is a multicomponent method with detection limits at the ppb level.

### 4.8 Industrial Contaminants

Industrial processes and their products are a major source of environmental burdening. Production processes are generally accompanied by the emission of considerable amounts of waste chemicals, solvents and by-products. Indeed, the final products, especially chemical ones such as pesticides, pharmaceuticals, dyes, oils, plastics and paints, are obvious potential polluters. Finally, several of these compounds may give rise to the formation of metabolites and oxidation and degradation products.

Notorious examples of hazardous waste compounds are the polychlorinated benzenes (PCBs), dibenzo-p-dioxins (PCDDs) and dibenzofurans (PCDFs) because of their high toxicity and persistency. Other well-known industrial contaminants are VOCs, polyaromatic hydrocarbons (PAHs), phenols and (metabolites of) pesticides.

Many IR spectroscopic methods are available for the analysis of this large variety of compounds. The determination of VOCs has been discussed in the previous section. A selection of the most important other compound classes is presented in the following sections.

### 4.9 Pesticides

Several IR spectroscopic methods have been developed for the determination of pesticides and their metabolites in aqueous matrices. Because of the limited sensitivity of IR in relation to the required limits of detection (0.1 to 1 µg L⁻¹ typical), the methods usually comprise a pretreatment such as liquid–liquid extraction (LLE), solid-phase extraction (SPE), thermal desorption and derivatization.

The potentials of GC/IR for the determination of pesticides have been summarized by Kalasinsky. Recent work on the combined GC/IR and GC/MS analysis of pesticides in surface and groundwaters from different locations in Lithuania has been carried out by Ellington et al. Organic constituents were extracted from the water samples by SPE on cartridges. Subsequently, the cartridges were transported to the laboratory, eluted by an organic solvent and injected on the GC. As well as triazines and Alachlor, several chlorinated and aromatic carboxylic acids were determined.

A similar method for the analysis of microcontaminants in tap and surface water has been developed by Hankemeier et al. After SPE extraction of 20 mL samples of water at site, the SPE cartridges are dried and brought to the lab. Next, the cartridges are desorbed on-line into the GC with 100 µL of ethylacetate using on-column large-volume injection interfacing. The IR detection is performed with a cryogenic sample storage GC/IR instrument. As can be seen from Figure 7(a), the Gram–Schmidt GC/IR chromatogram, reflecting the total IR absorption in the range 4000–6000 cm⁻¹ as a function of time, permits detection and identification of all eluting components. Functional group GC/IR chromatograms (Figure 7b), show elution of compounds that absorb in a preselected wavenumber region and can be used to monitor the presence of compounds with a specific structural element.

A variety of pollutants have been identified at 0.1 to 1 ppb level, the current alert and alarm levels for micropollutants. As an example of the performance of this system, the IR spectra of the pesticides Sulfotep and Diazinon, extracted from the chromatograms recorded from 1 ppb in Figure 7, are shown in Figure 8.

The utility of solvent elimination LC/IR for the determination of pesticides in aqueous matrices has been studied extensively by Somsen et al. Three different methods have been investigated for application to reversed-phase separations. The first method is an on-line post-column extraction of the analytes.
from the buffered aqueous mobile phase into the more volatile dichloromethane to improve the performance of the spray-jet LC/IR interface.\textsuperscript{42} This technique allows identification of phenylureas and quinones at a level of 50\(\mu\)g L\(^{-1}\). Improvement has been achieved by incorporation of a trace enrichment step using on-line SPE. With this method triazines and phenylurea herbicides can be identified at the alert level of 1\(\mu\)g L\(^{-1}\). The quality of the spectra obtained from the LC/IR analysis of a 100\(\mu\)L sample of river Meuse water, spiked at 2\(\mu\)g L\(^{-1}\), is shown in Figure 9. For 20\(\mu\)L injections, the analyte recovery is about 90\% which indicates that this method can be used not only qualitatively but also for quantitative purposes.\textsuperscript{43}

On-line trace enrichment combined with capillary column switching LC has proven to be a useful alternative for reversed-phase LC/IR when gradient elution separation is required. Post-column extraction cannot be applied because of the continuously changing composition of the mobile phase. However, these fluctuations are masked by addition of an excess of a volatile make-up liquid. The limit of identification of this method is about 20\(\mu\)g L\(^{-1}\) for triazines.\textsuperscript{44}

Optical-fiber sensing is suited to the analysis of high concentrations of chlorinated hydrocarbons and pesticides in water samples. Analogous to SPME, analyte enrichment is accomplished by a thin polymer film on the fiber surface. The detection limit is about 2 ppm for the pesticides Alachlor and Atrazine.\textsuperscript{45}

Finally, the same method of thermal desorption with subsequent measurement of the vapor phase, as applied for the determination of VOCs in soil, is applied for the determination of (semi)volatile pesticides when present in high concentrations.\textsuperscript{33}
Figure 9  IR spectra of the triazines (a) Simazine, (b) Atrazine, (c) Sebutylazine, (d) Propazine and (e) Terbutylazine detected in river water by SPE on-line trace enrichment LC/IR analysis. Water sample: 100 mL, concentration level 2 μgL\(^{-1}\). (Reproduced from *J. Chromatogr. A*, 756, G.W. Somsen, I. Jagt, C. Gooijer, N.H. Velthorst, U.A.Th, Brinkman, T. Visser, ‘Identification of Herbicides in River Water Using On-line Trace Enrichment Combined with Column Liquid Chromatography-Fourier-transform Infrared Spectroscopy’, 145–157 (1996) by permission of Elsevier Science Ltd.)

4.10 Phenols

Phenols and, particularly, nitrated and chlorinated phenols are an important class of contaminants in aqueous matrices. The compounds are released by the chemical industry as by-products, but are also formed as result of degradation of insecticides and herbicides. As result of exposure to UV radiation from the sun, oxidation and isomerization of phenols easily occurs which implies that a large number of nitro- and chlorophenol isomers is found in air, particulate matter, aerosols, wastewater effluents, surface water and groundwater. Several of these phenols are considered as high-priority pollutants and for that reason unequivocal identification is demanded.

Since IR spectroscopy is extremely powerful in the differentiation between isomers, IR spectroscopic methods have been used for this purpose on several occasions. Vredenbregt et al.,\(^{46}\) for example, applied cryotrapping GC/IR in addition to GC/MS, to distinguish between the ten molecular isomers of chloronitrophenol in surface water. Despite the absence of several reference standards, all isomers have been identified by interpretation of the complementary IR and MS data. The same sample storage GC/IR technique combined with GC/MS was used by Rodriguez et al.,\(^{47}\) to identify structural isomers of (poly)chlorinated phenol. After acetylation and preconcentration on graphitized carbon cartridges, 17 isomers have been identified.
Childers et al.\(^{(48)}\) employed matrix isolation GC/IR for the characterization of nitrocresols in air sample extracts. These products are formed by photodecomposition of NO\(_x\) and toluene in the atmosphere. A number of specific isomers have been identified by comparison with the GC/IR spectra of nitrocresol standards.

4.11 Polyaromatic Hydrocarbons

PAHs and their nitro derivatives are well established environmental contaminants which are invariably generated during combustion processes of fossil fuels. Unambiguous identification of PAHs and nitro-PAHs is important as the mutagenicity and carcinogenity among these molecules may differ considerably. The identification and structure elucidation relies primarily on GC/MS. However, especially in the absence of reference compounds, MS is insufficiently specific to distinguish between the relatively large number of isomers. GC/IR is a useful method to discriminate between PAH congeners that are difficult to distinguish by other methods. The relevance of such analysis has been demonstrated by Childers et al.\(^{(49)}\) and Kalasinsky et al.\(^{(50)}\) in methods for detecting and identifying PAHs and nitro-PAHs in urban air particulate matter.

Other applications of GC/IR for the analysis of PAHs are the characterization of aromatic isomers in marine sediments from mildly polluted sites in the Arabian Gulf area\(^{(51)}\) to endorse and confirm the results from GC/MS analysis and the confirmational analysis of PAHs in soil extracts in addition to a standard high-pressure liquid chromatography/ultraviolet (HPLC/UV)/fluorescence procedure.\(^{(52)}\)

Raynor et al.\(^{(53)}\) demonstrated that PAHs can also be determined adequately by capillary supercritical fluid extraction (SFE) combined with off-line FT/IR microspectrometry. Several PAHs have been identified in coal tar pitch samples after evaporation of the supercritical eluent and deposition of the separated analytes on a KBr disc.

Among the PAHs, the nonalterant cyclopentafused PAHs represent a unique class, being responsible for most of the genotoxicity of PAHs exhausts. Hence, their identification and the elucidation of their build-up mechanism is of major relevance. GC/IR has been used in addition to GC/MS for the identification of these PAHs and their intermediate PAHs. A cryogenic sample storage GC/IR interface has been applied to obtain sufficient sensitivity for subnanogram detection. Experiments have been carried out on standard compounds and on samples generated by in situ pyrolysis (T = 600–1100°C) of ethynyl PAHs as model compounds for mimicking combustion processes. Conclusions from GC/MS have been confirmed and, additionally, the molecular structures of previously unidentified components have been elucidated.\(^{(54)}\)

4.12 Dioxins, Dibenzofurans and Polychlorinated Biphenyls

PCDDs, PCDFs and PCBs are subject to considerable environmental interest due to the combination of their high toxicity and persistence. The three compound classes count 75, 135 and 209 congeners respectively, differing over six orders of magnitude in toxicity. It follows that highly sensitive univocal identification is required for these substances. For that reason, high-resolution GC/MS is the method of choice for this type of analysis.

Occasionally, however, additional IR spectrometric information is necessary to distinguish between the large number of possible molecular isomers, either for confirmational purposes in addition to GC/MS analysis, or for the identification of compounds that are to be used as analytical standards. As a consequence, many IR studies have been dedicated to the analysis of PCDDs, PCDFs and PCBs. Also, IR data are used to obtain information on the relationship between the toxicity and the geometrical structure of the molecules. Grainger and co-workers,\(^{(55,56)}\) for instance, demonstrated that the IR vapor-phase spectra point to a near planar geometry for the highly toxic laterally substituted isomers, and a more tetrahedral type of geometry for the less toxic isomers in which the aromatic rings have lower electron withdrawing capacity. These conclusions are consistent with the data obtained from X-ray crystallography.

The importance of the identity conformation of standard materials for reference purposes has also been commonly acknowledged. Examples are the characterization of PCBs\(^{(57,58)}\) and chlorinated and brominated dibenzodioxins and dibenzofuranes,\(^{(59)}\) by matrix-isolation GC/IR, and the recording of the GC/IR reference spectra of all 209 individual PCB congeners.\(^{(60)}\) The discriminative properties of IR spectrometry for this type of analyte are well illustrated by the spectra of 5 congeners of chlorinated and brominated dibenzodioxins in Figure 10.

Applications of IR spectrometry to the analysis of PCDDs, PCDFs and PCBs in real-life samples are scarce and restricted to samples with high concentrations. A recently published example is the GC/IR analysis of extracts of fly ash from a municipal waste incinerator to confirm the results from GC/MS.\(^{(61)}\) PCDD- and PCDF-congeners have been identified unambiguously at high picogram level as result of the complementary information from both techniques.

Barbour, ‘Characterization of Brominated and Bromo/chloro Dibenzo-p-Dioxins and Dibenzofurans by Gas Chromatography/Matrix Isolation-Infrared Spectrometry’, 1285–1290 (1992) by permission of Elsevier Science Ltd.)

4.13 Oils and Greases

For many years, the quantitative determination of mineral oil in water, soil and sediment samples by IR spectrometry has been a widely applied standard protocol for environmental and QC. The methods are based on the extraction of the hydrocarbons by an apolar solvent, followed by elimination of possibly co-extracted polar substances by means of Florisil, and subsequent measurement of the absorption maxima of the C–H stretching bands in the extract. The limit of detection is in the order of 0.05 to 1 mg L⁻¹, depending on the extraction solvent and the pathlength of the liquid cell (1–5 cm typical). An example of the usual absorption pattern of a mineral oil is shown in Figure 11.

Up till now the extraction, prescribed in the protocols, has been carried out with halogenated hydrocarbons such as carbon tetrachloride and freon-113 as these solvents are IR transparent in the relevant wavenumber region 3200–2700 cm⁻¹. However, as result of the ozone-depleting effects of chlorinated fluorocarbons (CFCs), research is going on to alternative extraction methods without the use of these solvents. Several excellent alternatives for extraction and preconcentration have been proposed, such as adsorption filtration, SPE, SFE, microwave-assisted extraction (MAE) and LLE in strongly reduced liquid volumes or in nonhalogenated solvents. In parallel, ATR and DRIFT have been tested as alternative methods for the extinction measurement of the alkyl bands after evaporation of the solvent. The performances of several of the new methods are comparable or even better than the conventional ones with detection limits in the order of 0.005 ppb and a recovery of 90%.

Another alternative for the relatively elaborate extraction methods is direct screening by optical-fiber sensing. This in situ method is very fast but can only be applied for highly contaminated wet soils.
4.14 Soil Characterization

IR spectrometry is commonly applied for the characterization of soil humic acid (HA) and fulvic acid (FA) fractions. HA and FA substances are complex organic macromolecules formed by degradation of biotic material such as cellulose, lignins, peptides, saccharides, etc. The large variety in the precursor structure combined with the many different parameters affecting the degradation process, results in an enormous diversity of the chemical and physical properties of humic substances. These properties play an important role in environmental analysis of xenobiotic compounds and for that reason the characterization is an important task. IR spectroscopy is a useful method for this purpose, particularly in the determination of the oxygen contents of humic and FAs. Information on the oxygen contents of both untreated as well as fractionized HAs and FAs can be derived from the position and the band pattern of the OH stretching bands around 3300 cm\(^{-1}\), the strong absorbing symmetric and asymmetric C(\(\equiv\)O)–O– stretching vibrations at 1600 and 1400 cm\(^{-1}\) and the \(-\text{C}–\text{O}–\text{C}\) bands in the region 1200–1000 cm\(^{-1}\), which are correlated to the presence of hydroxylic, carboxylic and ether groups, respectively.\(^{65,66}\) Examples of the IR spectra of peat HA fractions are given in Figure 12.

An IR method, closely related to characterization of HA fractions, is the analysis of residual fractions that remain after microbiological degradation of contaminated soil.\(^{67}\) In this application, IR spectrometry is used to determine oxidation products of the original contaminants.

Another way to classify humic substances is by pyrolysis GC/IR.\(^{68}\) With this technique, HA and FA fractions are characterized by the identity of the different pyrolysis products such as acids, lactones, alcohols and phenols, and their relative abundance.

4.15 Inorganics and Asbestos

Occasionally, IR is used to determine the quantity of specific inorganics such as minerals and nitrates by means of conventional KBr measurements, DRIFT or photoacoustic IR.

A specific application is the analysis of asbestos (hydrated silica fibers) which is of concern owing to its assumed lung cancer causing properties. Although microscopy is usually the principal method for the determination of the type of asbestos, IR is often used for additional identification and confirmation. As demonstrated by Lang et al.,\(^{69}\) IR can be used for the quantification as well. A method has been developed to quantify asbestos down to 0.01% by weight using an ashing technique to eliminate the cellulose matrix prior to absorption measurement.

4.16 Polymer Characterization

For obvious reasons, the recycling of sorted plastics has a number of advantages over unsorted regeneration. IR is highly suited for the identification of polymers and for that reason the application of IR for polymer recognition in waste industry is logical. At present several methods for automated plastic-waste identification are being employed. All applications are based on a fast, remote recognition of polymers in a stream of waste.\(^{70}\)
Examples of IR classification of (co)polymers for recycling purposes are found in the automobile industry, the regeneration of electronic equipment, the identification of waste carpet materials and in sorting plastics from municipal solid waste. The latter combines the spectral IR and NIR information with additional geometric information by means of a focal-plane IR imaging system.

4.17 Quality Assurance

As already noted, IR spectrometry is commonly used for confirmational purposes and identity control of analytical standards prior to performing qualitative and quantitative analysis. Confiramional analysis is important since unambiguous identification of substances with suspected toxic properties is subject to stringent forensic and regulatory requirements. Identity control is relevant as the growing importance of good laboratory practice (GLP) has increased the prescription of IR for the QC of analytical standards.

In general, the analytical procedure and the criterion for confirmation are described into detail in a Standard Operating Procedure (SOP) in accordance with requirements as proposed by the International Organization for Standardization (ISO). Several criteria and algorithms have been developed to express the similarity between two spectra in a reliable and useful number. Nowadays, the software of virtually all IR instruments offers this possibility while also less stringent peak-matching requirements as well as criteria based on neural networks have been proposed as decisive criteria to confirm the identity of a standard or an analyte.

4.18 Chemometrics and Model Studies

Nowadays, chemometrics plays a very important role in IR spectroscopy. The fact that FT/IR instruments are inherently equipped with fast processors and large storage capacity for data acquisition, processing and manipulation has made it considerably easier to use chemometric techniques like discriminant analysis (DA), principal component analysis (PCA), partial least squares (PLS) regression and artificial neural networks (ANN). On the other hand, the need for application of these techniques has been urged by two developments. Firstly, the current instrumentation produces increasing amounts of spectral data in shorter time and spectra are currently obtained within a tenth of a second. Secondly, the development of two- and three-dimensional mapping facilities and the coupling to GC and LC, has manifolded the number of spectra to be handled. In order to facilitate or even admit the interpretation of this enormous amount of information, chemometrics are practically indispensable and have, therefore, become common sense in modern IR spectroscopy. Data reduction and data storage methods are applied to reduce the large amount of data to feasible proportions in terms of desk and memory space while multivariate calibration techniques have been incorporated into the standard instrument software for data manipulation and simplification of the interpretation. Besides, expert systems have been developed to enable unskilled spectroscopists to take advantage of unknown possibilities of IR spectrometry. Examples are the chemometrical systems that are used to assist in the structure elucidation of unknowns.

Model studies are a valuable method to predict the course of processes when only a limited number of data is available or in case extended studies cannot be performed for practical reasons. Particularly, in large-scale processes such as environmental exposure and risk assessment, computerized models are indispensable. Several models, partly or fully based on IR spectroscopic data, are currently used for this purpose. An important additional advantage of IR spectrometry is the possibility to perform real-time and in situ measurements which enables the development and the validation of a model not only in the laboratory but also in real-life situations.

A good example are the computerized models that are used in studies of the greenhouse effect. These models take into account a variety of parameters such as the atmospheric and earth temperature, cloud cover, geographic coordinates, weather conditions and the composition of the atmosphere as a function of the altitude. Obviously, IR remote sensing is very well suited to provide the required qualitative and quantitative data of greenhouse and other gases. Moreover, the same technique can be used for the validation by monitoring the actual atmospheric composition and (photo)chemical processes.

Specific examples of model studies based on IR data are those of Collette and Nelson et al. The first one applied PLS modeling of IR spectral data, to predict chemical and physical constants and distribution coefficients of a number of pollutants in order to estimate their environmental fate. The second one carried out a model study to determine the parameters that affect the formation of toxic constituents during incineration of wastes.

5 CURRENT POSITION AND FUTURE DEVELOPMENTS

At present, IR spectroscopy is a viable method for many applications in environmental analysis. The merits of the technique lie in its versatility and in the unique fingerprinting properties of the spectra. The first makes...
IR the principal method for remote sensing and in situ measurements as illustrated by the applications in atmospheric studies and the classification of polymers. The second makes it, in principle, the method of choice for unambiguous identification. In trace analysis, however, mass spectrometry is superior in sensitivity and ease of operation and for that reason the role of IR is mainly restricted to QC and confirmational purposes.

Future applications should be seen in relation to developments in hard and software. The recent introduction of diode array detection in IR spectrometry is a good example of the ongoing attempts at innovation. Further development of this type of detection can be expected. Research will also focus on improvement of the sensitivity by means of dedicated detectors and tunable IR laser technology. At short notice, the ongoing demand for fast and robust methods will lead to the further development and optimization of dedicated, low-cost sensor type of instruments, particularly suited for routine and field measurements. As such, the growing interest in NIR spectrometry for routine tasks, currently performed with mid-IR techniques, will most likely continue.

Finally, it should be noted that the improvement of IR technology will be attended by similar developments of other analytical techniques. For that reason, the choice for application of an IR spectroscopic method has always to be judged in relation to the potential of alternatives which includes economical and practical considerations such as the availability of instrumentation and expertise.

INFRARED SPECTROSCOPY IN ENVIRONMENTAL ANALYSIS

45. F. Regan, M. Meaney, J.G. Vos, B.D. MacCraith, J.E. Walsh, ‘Determination of Pesticides in Water Using

Capillary electrophoresis (CE) is a very useful technique which involves the separation of charged species (molecules) on the basis of their movement under the influence of an applied electric field in a capillary format. CE has been developed into rapid, highly effective techniques with extremely high separation power ($10^5$–$10^7$ theoretical plates) and high mass sensitivity (femtomole to zeptomole amounts of substances in nanoliter to picoliter sample volumes) with high potential for separation in the analysis of environmental sample. CE has been compared with ion chromatography (IC) in the inorganic analysis of environmental samples since inorganic ions are usually separated by IC with suppressed conductivity detection. The advantages of CE compared to IC are speed, resolution, and the lack of a need for gradient elution. Operating costs are considerably lower, since ion-exchange columns are usually expensive. In application, however, limitations imposed by the lack of detection sensitivity complicate the technique’s use and impede its wide acceptance. However, as instrumental development continues (especially in detection mode and other techniques for manipulating sensitivity), this limitation will most likely be overcome and a diversity of inorganic species in real samples has already been proved to be amenable to the analysis by CE, and more can be expected in the years ahead.

In this article, to understand how CE can be applied to separation and detection of inorganic ions of environmental sample, the basic principles underlying this technique and the operating parameters of CE for inorganic analysis of environmental samples are presented. For trace analysis of environmental samples, methods for manipulating the sensitivity and selectivity control for metal ions are discussed. Techniques such as the coupling of CE with inductively coupled plasma mass spectrometry (ICPMS) are also discussed. Specific applications in real world samples which have complex matrices as well as artificial samples or reference materials are offered to demonstrate the potential of CE in the analysis of environmental pollutants.

1 INTRODUCTION

Inorganic pollutants of environmental samples comprise a variety of metal species and small anions. Since at trace level they are usually in unknown and variable matrices as various chemical states, a sensitive and selective technique is always required for their determination.

CE is an emerging technique in this area. CE possesses many unique advantages for the analysis of environmental pollutants, which include small sample volumes, high mass sensitivity, high separation efficiency, low cost columns, easy rinsing of the column, low consumption of reagents, simple methodology, short analysis time, etc. CE, which was initially developed for the separation and determination of biopolymers such as proteins, peptides and organic compounds, has been rapidly introduced into the analysis of inorganic ions since the early 1990s and has become a promising technique for the
inorganic analysis of environmental samples. The active research in CE reflects the expectation of this method for the replacement or supplement to high-performance liquid chromatography (HPLC) or IC with suppressed conductivity detection, which is the most popular method at present in this area. However, the use of CE as a routine quantitative technique in environment analysis is still limited because of the low concentration sensitivity of CE due to the small sample volume. However, as instrumental development continues (especially in detection mode and other techniques for manipulating sensitivity), this limitation will most likely be overcome.

In order to give a better understanding of how CE can be applied to the separation and detection of inorganic ions of environmental samples, this article will present the basic principles underlying this technique and operating parameters of CE for the inorganic analysis of environmental samples. Methods for manipulating the sensitivity (important for trace analysis) and selectivity control for metal ions are also introduced. Specific applications in real world samples as well as artificial samples or reference materials will be offered to demonstrate the potential of CE in the analysis of environmental pollutants.

The basic principles and instrumentation relevant to the separation of inorganic ions and applications to environmental analysis are discussed in several books

and reviews.

There are over 100 reviews about other specific issues related to CE, such as detection technique, derivatization, mathematical modeling, etc. Among them, some reviews on environmental application are recommended to the interested reader.

CE can be performed in various modes with differing mechanisms of separation, such as capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), micellar electrokinetic capillary chromatography (MEKC), capillary electrochromatography (CEC), capillary isoelectric focusing (CIEF) and capillary isotachophoresis (CITP). In this article, CE represents CZE with an on-line ultraviolet/visible (UV/VIS) absorbance detector unless specifically defined.

2 BASIC PRINCIPLES

2.1 Capillary Electrophoresis System and Operating Parameters

The general mechanism for CE separation is based upon differences in the mobility of solutes transported along a capillary tube by a high dc voltage. In the simple system shown in Figure 1(a), both ends of the fused silica capillary, filled with a suitable electrolyte, are immersed into two reservoirs of the same electrolyte. The capillary is normally 50–100 cm long with an internal diameter of 25–100 µm. A high potential difference of 20–30 kV is applied across two platinum electrodes in the reservoirs.

The sample (several nanoliters) is injected into the capillary and the components of the sample migrate towards the negative electrode. Because the cross-section of the capillary is small, a high surface to volume ratio is achieved. This dissipates heat, generated by joule heating, to the surroundings. Convective mixing within the capillary is, therefore, not significant and band broadening is minimized, resulting in efficiencies of several hundred thousand plates.

Electroosmotic flow (EOF) of the solvent occurs in the capillary because an electric double layer is formed at the capillary surface (Figure 1b). The fused silica capillary surface has a net negative charge owing to the dissociation of the functional groups on the capillary surface. Positive ions are attracted from the buffer solution and an electrical double layer is formed at capillary surface. When an electric field is applied, mobile positive ions, present at the capillary surface, are attracted to the negative electrode, and solvent molecules are transported concurrently. A unique feature of EOF in the capillary is the flat profile of the flow, which is beneficial because it does not directly contribute to the dispersion of solute zones.

The movement of analyte ions is caused by the combination of electrophoretic mobility of the analyte ion and the EOF of the solvent. Therefore, depending on whether or not the electrophoretic mobility has a similar direction to the electroosmosis, the separation mode in CE is divided into coelectroosmotic or counterelectroosmotic modes. Within a bare fused-silica capillary, small cations which are attracted to the negative electrode migrate at a velocity greater than the EOF (coelectroosmotic flow). Conversely, anions are repelled by the cathode and migrate more slowly than the EOF (counterelectroosmotic flow). Neutral species move with the EOF and are generally unseparated unless some modification to the surface charge of the analyte is made by
the addition of a surfactant (MEKC). The direction of the EOF can be decreased or reversed to achieve reasonable analysis times for small anions. The polarity of capillary wall can be modified by the addition of EOF modifiers.

A traditional CE detector that is commercially available is the on-column UV/VIS spectrophotometer. The small capillary diameter of CE creates a thin beam path for on-column UV/VIS detection. This creates a sensitivity problem in the study of environmental samples which usually require the detection of species in trace or ultratrace levels. To overcome this problem, many detection techniques have been developed for CE. Among them laser-induced fluorescence (LIF) and amperometric detectors are commercially available.

Since most small cations and anions lack the necessary chromophore properties allowing a straightforward detection at any wavelength above 200 nm, indirect detection is often employed for the detection of ultraviolet (UV) transparent ions. A UV-absorbing co-ion (or probe co-ion) is present in the background electrolyte (BGE) and detection is accomplished as a result of displacement of the probe ion by analyte ions. Commonly used electrolytes for anion determination are chromate and pyrromellitate and for cation determination, 4-aminopyridine, imidazole and creatinine.

2.2 Electrolyte Condition

For many ions, the mere combination of electrophoresis and electroosmosis does not offer a sufficient selectivity for a satisfactory resolution from other peaks in the sample mixture. It is required frequently to refine CE separations by utilizing analyte interactions with suitable components of the electrolyte. Optimization of the CE separation can be difficult due to the wide array of parameters and variables that must be controlled. However, it is worth understanding several possible factors contributing to the selectivity of CE and its trend for the separation of inorganic ions. The pH level, concentration, component of electrolyte, additives, and EOF are regarded as the most important factors. Their influence on the selectivity is quite different depending on the sample status, especially on the sample polarity.

2.2.1 pH

The pH of the separation electrolyte must be carefully selected. While cationic separations are mostly performed at pH 3–5, anionic separations are seldom carried out using an electrolyte with a pH value below 7. This fact can be attributed to the different behaviors and properties of cations and anions in aqueous solutions. Cations, especially those of transition metals and some of alkaline earth metals, readily precipitate at high pH. In addition, the electrolyte constituents for providing an indirect detection mode for cations mostly have pKₐ values in the low pH range. To match the mobility of the sample cations, the pH has to be sufficiently low so that almost all the electrolyte constituents are present as cations. On the other hand, for the determination of anions, the electrolyte pH has some effect only on the anions of weak acids. In acidic conditions, serious tailing and unacceptably long migration time occurs for the anions of weak acids in coelectroosmotic mode, e.g. acetate and carbonate. The long migration time results from the effect of EOF due to the change of pH. The EOF rate increases with the pH because of a large degree of dissociation of silanol groups on the capillary wall.

2.2.2 Concentration

The concentration of carrier electrolytes affects the selectivity. In general, a longer migration time can be expected with increasing concentrations of electrolyte. This is explained by increases in separation currents and the corresponding weakening of the electric field in the capillary filled with carrier electrolytes. Sample stacking effects can be obtained at an electrolyte concentration 10–100 times higher than the sample concentration. However, a high concentration of electrolyte will give the deteriorating joule heating effect which makes bubbles inside the capillary and sometimes results in a breakdown of voltage.

2.2.3 Selection of Electrolyte Component

Depending on the detection mode and interested ions, the background electrolyte is selected. When indirect UV/VIS detection is used, the electrolyte ion must be chromophoric as discussed above. A shift from one electrolyte to another is more commonly dictated by one of the conditions of CE, prescribing the match of mobilities between analyte ions and electrolyte cations. When the electrolyte anion has a lower mobility than the solute anions, an asymmetrical, fronting peak may result. This is because the high mobility solute anions tends to migrate ahead of the sample zone. Conversely, when the electrolyte anion has a higher mobility than the solute anion, a tailing peak results. Distinct tailing, usually observed for most carboxylates in chromate, can be avoided by choosing a phthalate-containing electrolyte. The selectivity of the separation of low mobility anions can be modified even to the complete reversal of order of migration by switching from coelectroosmotic to the counterelectroosmotic mode by addition of EOF modifier.
2.2.4 Additives

The use of additives in CE lead to dramatic changes in separation power. Micellar, complexing reagents, EOF modifiers, and organic solvents are various types of additives that have been used to control the selectivity of the separation.

The addition of an organic solvent to the electrolyte will change migration times and selectivity. The manipulation of selectivity use of organic solvents offers these advantages due primarily to an effect on the solvation of cations and on the ion pairing of anions. The addition of organic solvents to carrier electrolytes can lead to longer migration times with increasing concentrations of a solvent and the change of migration order of anions. It is assumed that organic solvents tend to shift ion pairing equilibrium to the right for anions. For cations, the solvation effect is accomplished by the changes in charge density, since in comparison to aqueous electrolytes, polar organic solvents affect the actual size of ions via forming ion solvent dipole bonds. The mobilities of solvated cations or ion paired anions are also influenced by changes in the viscosity of water–organic mixtures. One particular advantage of organic solvents, especially with regard to ionic complexing additives, is that the ionic strength of the capillary electrolyte is not increased, which prevents possible thermal effects. Among a variety of organic solvents that have been studied with regard to their suitability for CE, methanol, N-methylformamide, dimethylformamide, dimethyl sulfoxide and acetonitrile seem to be particularly useful. More detailed information on the important properties of organic solvents for use in nonaqueous CE separations were summarized in a review.

The effect of micelles, complexing reagents, and EOF modifiers will be discussed in other sections.

2.2.5 Electroosmotic Flow

The regulation of the rate of EOF is another way to enhance the separation in CE. Although the EOF does not contribute to the selectivity changes (at least for the analytes of the same charge), it has been demonstrated to be useful in manipulation of the resolution, in particular, in micellar-mediated CE systems. Since the migration velocities of small, charged ions exceed the velocity of the EOF, the coelectroosmotic separation principle is usually preferred for inorganic analysis. In uncoated capillaries, the direction of the EOF is from the anode to cathode, which means that only cations can be separated without modification of the capillary wall. The direction of the EOF has to be decreased or reversed to achieve reasonable analysis times for small anions. EOF modifiers such as cetyltrimethylammonium bromide (CTAB), tetradecyltrimethylammonium bromide (TTAB), or hexamethonium hydroxide (HMH) have been used for this purpose.

2.3 Detection System

2.3.1 Photometric Detection

Currently, most commercially available instruments for CZE are equipped with spectrophotometric detectors, in particular UV-absorbance detectors. This detector is preferred because it offers minimal loss in separation efficiency and easy set-up. As most small cations and anions lack the necessary intrinsic chromophore properties allowing a straightforward and sensitive detection at any wavelength above 200 nm, their detection generally requires derivatization using a suitable chromophore prior to separation. Otherwise indirect UV detection should be applied. For analysis of metal ions, derivatization can also be used to enhance the selectivity. Details of the method will be presented in the following section.

As the key to the latter approach is the displacement of a highly absorbing electrolyte co-ion, a close mobility match to the analyte ion is required; otherwise asymmetrical peak shapes are generated. Commonly used electrolytes for anion determination are chromate and pyrromellitate and for cation determination, 4-aminopyridine, imidazole and creatinine. While UV/VIS absorbance detection is the most common, straightforward, means of accomplishing on-column detection for CE, achievable sensitivity is limited due to short beam pathlength. Usually the limit of detection (LOD) is below the order of 10 mM. It is not sensitive enough for environmental trace analysis. Even so, CE still has an impressive mass sensitivity, which can compete with the best HPLC system because of a very low injected sample volume. To enhance concentration sensitivity for CE, various approaches have been developed. These approaches include preconcentration by solid phase extraction (SPE), on-line preconcentration by isotachophoresis (ITP), on-column preconcentration by sample stacking, and use of detection cells with extended optical pathlength. Albin et al. have presented a review in this field.

As UV detectors, photomultipliers or diode array detector (DAD) is used. Photomultiplier has a higher sensitivity than DAD while DAD offers a full spectrum. Since inorganic ions do not have a unique UV/VIS spectrum, photomultiplier is desirable since it usually gives more sensitive results.

As more sensitive optical detection methods have been pursued, fluorescence has become the most popular, as demonstrated by the numerous applications described in a recent review. LIF can provide LOD several orders lower than UV absorbance. Using direct fluorescence, detection limits in the attomole to zeptomole range and...
even single molecule detection has been reported for polyaromatic hydrocarbons and proteins. In the field of study of metal ions, direct fluorescence detection of complexed metal ions was accomplished by Swaile and Sepaniak. Using 8-hydroxyquinoline-5-sulfonic acid (HQS), which fluoresces only when complexed, Mg$^{2+}$, Ca$^{2+}$, and Zn$^{2+}$ can be detected in the ppb range.\textsuperscript{35} More commonly, indirect fluorescence detection techniques were used for analyses of metal ions, although the number of studies has been rather limited. Using a quinine sulfate electrolyte buffer system for indirect fluorescence detection and electrokinetic detection, alkali and alkaline earth metals were detected at femtomole levels. Indirect detection and electrokinetic detection, alkali and alkaline metals used for analyses of metal ions, although the number of studies has been rather limited. Using a quinine sulfate electrolyte buffer system for indirect fluorescence detection and electrokinetic detection, alkali and alkaline earth metals were detected at femtomole levels. Indirect LIF detection for capillary separation was reviewed by Yeung and Kehr.\textsuperscript{36}

Indirect LIF detection is also possible with MEKC. The sensitivity relies upon the different quantum efficiency of the fluorescent reagent in the two phases. Generally, the quantum efficiency of the fluorescent reagents is significantly enhanced in the micellar phase, and the displacement of it from the micellar phase to aqueous phase by the analytes caused a concomitant reduction in the fluorescence signal.

Chemiluminescence (CL) detection involves the reaction of the analyte, or some species produced by the chemical or enzymatic reaction of the analyte with a CL reagent to produce light in the detection cell. The most common CL detection system utilizes the hydrogen peroxide–luminol reaction, in which the hydrogen peroxide is a by-product of a chemical enzymatic reaction of the analyte. Alternatively, a variety of metal ions catalyze the reaction of hydrogen peroxide and luminol in alkaline solution and can thus form the basis of direct\textsuperscript{37} and indirect\textsuperscript{38,39} CL detection. For high sensitivity detection of metal ions separated by CE, Huang et al.\textsuperscript{37} combined the incorporation of luminol into the separation buffer with post-column mixing of the hydrogen peroxide solution immediately before passing through the detection region. They reported the best system detection limits for Co(II) (20 zmol, $5 \times 10^{-13} \text{ M}$) while other metals gave mass detection limits ranging from 2 amol to 100 fmol. Average reported plate counts were over 400 000, indicating no compromise in separation performance due to the post-capillary mixing of CL reagents.

2.3.2 Conductivity Detection

In addition to detection methods based on spectrophotometric principles, CZE combined with a conductometric detector has been presented in a number of published papers.\textsuperscript{40–48} Different detector configurations suitable for both on-column and end-column conductivity detection have been reported but only the latter technology is commercially available to date.

Compared to CE with UV detection, devices equipped with conductometric detection offer significant enhancement in performance and sensitivity especially for the analysis of low molecular mass ionic compounds. Whereas in CE with UV detection the suitability of a certain carrier electrolyte strongly depends on its UV absorbivity, low-conductivity buffers or buffers suppressible with common methods are used in the case of CE devices equipped with non-suppressed or suppressed conductivity detection respectively. In non-suppressed conductivity detection, the so-called Good’s buffer components\textsuperscript{47,48} proved to be suitable carrier electrolytes for a number of separation problems.\textsuperscript{42–45,49,50} Because the first commercially available CE device offering the possibility of conductivity detection was introduced recently,\textsuperscript{45} only a small number of papers dealing with the applicability of this system for the analysis of real samples has been published. Since the high sensitivity inherent to electrochemical detection (ED) does not depend on the scale of measurement, ED could become an important alternative detection mode for CE.

Conductivity detection for CE was addressed during the covered period.\textsuperscript{51,52} A simple conductivity detector with detection limits in the nanomolar range was demonstrated.\textsuperscript{51} Suppressed conductivity detection for CE was discussed in terms of its compatibility with various electrolyte systems.\textsuperscript{52}

2.3.3 Inductively Coupled Plasma Mass Spectrometry

ICPMS has great potential usefulness owing to a very low detection limit obtainable without preconcentration and a large dynamic range. It is noted that there is no need to separate species electrophoretically that contain different elements from each other as the ICPMS detector serves to identify the metals present individually. Speciation studies are of primary interest for CE coupled with ICPMS as only ions, complexes or molecules containing the same element need to be separated. Therefore, for different element ions of similar mobilities, electrophoretic resolution will be poor but the ions will be adequately identified by the ICPMS element specific detector. The coupling of CE with ICPMS is relatively new and interface designs are still being developed and evaluated. The use of direct injection nebulization and other low flow nebulizers are, without a doubt, the way forward if electropherographic resolution is to rival that obtained with UV detection.

The coupling of CE with ICPMS for elemental analysis has been reported by several groups.\textsuperscript{53–56} Two major challenges for the coupling of this technique need to be addressed. They have been described by Tomlinson et al.\textsuperscript{57} The flow-rate (typically of the order of nL min$^{-1}$) and low sample volume of a typical CE separation is the
first potential problem, as most nebulizers for ICPMS are designed to operate at flow-rates in the mL min\(^{-1}\) range. Glass frit,\(^{(55)}\) direct injection, oscillating capillary, ultrasonic\(^{(54)}\) and Meinhard nebulizers\(^{(56)}\) are suitable for such low flows. Another factor to consider is that the end of the capillary will no longer be immersed in a buffer reservoir upon coupling to ICPMS and a method of “grounding” the electrode must be achieved. The construction of such an interface is an important consideration so that high transport efficiency is achieved.

### 3 SELECTIVITY CONTROL BY COMPLEX FORMATION

The electrophoretic mobility in CE, \(\mu_{\text{eff}}\), is originally determined by the intrinsic solute parameters, effective charge to size shown in Equation (1):

\[
\mu_{\text{eff}} = \frac{q_i}{6\pi\eta r_i} \tag{1}
\]

where \(q_i\) is the charge of hydrated or complexed ion, \(r_i\) is its size (the hydrodynamic radius) and \(\eta\) is the viscosity of the electrolyte medium. In the separation of metal species such as alkaline metals, alkaline earth metals, transition metals or lanthanides, the electrophoretic mobilities of most metal ions or metal complexes are similar in magnitude since they possess nearly identical charge and size. To improve separation efficiency of metal ions in CE, altering either the effective charge or size of a metal species or both is required. This can be done by the complex formation of the sample during (on-capillary) or before electrophoresis (pre-capillary), as well as routine practice of compositional changes of the carrier electrolytes resulting in ion dissociation or change of solvation effect, etc. Therefore a distinct feature of the separations of metal ions by CE is the frequent use of ligands to form complexes with the metal ions.

Classifications of complexation reaction are based on either their place in the final analytical set-up: before (pre-capillary), or during (on-capillary) the electrophoretic separation; or the degree of metal ion complexation due to the thermodynamic stability of the metal complexes: partial or total complexation.

In the partial complexation approach, usually on-capillary reaction with weakly complexing ligands such as the variety of carboxylic and hydroxycarboxylic acids takes place. In this case, the complexation reaction should be fast and quantitative to be detected within the time of typical CE run, and the complexing agent should be stable. Separation selectivity is most easily manipulated in this mode coupled with indirect photometric detection. The simultaneous separations of the greatest number of metal ions have been achieved using this approach.

On the other hand, in the total complex approach, metal ions are completely transformed into moderate to strong complexes usually in pre-capillary mode or rarely on-capillary mode. Adapting pre-capillary complexations, there are some advantages such as (i) the large flexibility in optimizing the reaction conditions, e.g. the possibility of selecting solvents which are not compatible with the CE system, or (ii) no limitation to the reaction kinetics, provided a single derivative is formed with the analyte, (iii) the conditions during complexation do not have to be compatible with the electrophoretic buffer, and (iv) the availability of a wide variety of complexing agents. However, in this case, control of separation selectivity and maintenance of good peak shapes is an intriguing task. Use of the total complexation mode with ligands such as ethylenediaminetetraacetic acid (EDTA) or cyclohexane-1,2-diaminetetraacetic acid (CDTA) has made possible the separation of some higher-valent metal ions which cannot be separated in other systems. However, the generally low sensitivity of direct photometric detection remains a weak point of this approach. Therefore, new metallochromic ligands with high absorbing characteristics, which react with as many metal ions as possible and form a single complex only with each metal, should be applied.

#### 3.1 Partial Complexation

When a complex-forming equilibrium is established by introducing a weak complexing reagent into the electrolyte, partial complexation is set up. As a result, several different complexes of metal ions may exist simultaneously due to stepwise complexation. For an analyte species present in several forms which are in equilibrium with rapid kinetics of interchange between the forms, the effective mobility of the analyte is defined as the weighted average of the mobilities of each of the forms\(^{(58,59)}\) (Equation 2):

\[
\mu_{\text{eff}} = \sum \mu_i \alpha_i = \frac{\sum \mu_i [\text{ML}_i]}{\sum [\text{ML}_i]} = \frac{\sum \mu_i \beta_i [\text{L}]^i}{\sum \beta_i [\text{L}]^i} \tag{2}
\]

where \(\mu_i\) is mobility and \(\alpha_i\) is the distribution coefficient of the form \(i\), \([\text{ML}_i]\) is the concentration of the complex \(\text{ML}_i\), \([\text{L}]\) is the concentration of the form of ligand forming the complex and \(\beta_i\) is the overall stability constant (ML\(_0\) = M, \(\beta_0 = 1\)). Therefore, based on the nature of the complexing reagent and the concentration of free ligand, usually dependent on the pH of the electrolyte, effective mobility of complexed metal ions can be controlled.
Affecting the degree of complexation and resulting migration velocity is the concentration of the complex-forming reagent, [L]. The concentration effects on the electrophoretic mobilities of metal ions have been studied in several studies. The majority of organic acids used as partial complexing reagents are weak acids and hence undergo acid–base dissociation equilibria in the electrolyte buffer. In the case of a monoprotic acid, Equations (3) and (4) apply:

\[ \text{HL} + \text{H}^+ + \text{L}^- \rightarrow \text{H}_2\text{L}^- \quad (3) \]

\[ K_a = \frac{[\text{H}^+][\text{L}^-]}{[\text{HL}]} \quad (4) \]

in which \( K_a \) is the acid dissociation constant of HL. Consequently, it is not the total concentration of a given reagent added to the electrolyte but the concentration of free ligand which determines the ability to differentially reduce the mobilities of metal ions. Also the pH of the electrolyte is another important factor since the concentration of free ligand is dependent on it.

A variety of carboxylic and hydroxy-carboxylic acids are found to be suitable as partial complexing reagents for the separation of metal cations. Of various complexing reagents tested, \( \alpha \)-hydroxy-isobutyric acid (HIBA) has been most popularly used. Remarkable separation results for alkali, alkaline earth, transition and rare earth metal ions are shown in Figure 2. Lactic acid also appears to be advantageous in terms of separation selectivity and citric, malonic, glyyclic, tartaric and oxalic acids have been used to give good selectivity. A comparative study of 10 carboxylic acids as complexing agents showed that oxalate and citrate exhibited the largest selectivity changes, and the optimum pH for separating metal ions in the presence of the complexing carboxylic acid was close to the \( pK_a \) of the acid. A noticeable improvement of the separation can be obtained by the combination of two ligands which possess different abilities for the complexation, for example, HIBA and acetate or lactate and HIBA. Using a lactic acid and 18-crown-6 buffer with imidazole for indirect UV detection, alkali, alkaline earth, and transition metal cations have been simultaneously separated by CE.

3.2 Formation of Inclusion Complexes

Enhanced selectivity for the separation of alkali and alkaline earth cations can be obtained from a somewhat different partial complexation: inclusion complexation. The formation of inclusion complexes is observed in molecules having a well-defined cavity in their structure such as the crown ether. The dimension of the cavity in crown ethers makes those compounds ideally suitable for selective interactions with alkali and alkaline earth cations. According to this complexation principle, macrocyclic ligands magnify differences in mobility of only certain cations like \( \text{K}^+ \), \( \text{Ba}^{2+} \), \( \text{Sr}^{2+} \) which interact specifically with 18-crown-6. As the charge of a metal ion remains unchanged during the complexation, the retardation effect on the migration velocity is owing to the charge density alterations for much bulkier crown-complexed cations. Apart from the resolution of ammonium/potassium and calcium/strontium pairs, other changes in selectivity, most dramatically the large change in migration time of barium, are noted.

Since the crown ether ligands are electro-neutral, free ligand concentration and thereby complexation is virtually unaffected by the pH and the only electrolyte variable to improve the selectivity is the total concentration of crown ether. In general, higher electrolyte concentrations of crown ether are favorable as they widen the range of effective mobilities of the cations.

Macrocyclic polyethers, mostly 18-crown-6, are commonly used in combination with a weak complexing acid in order to separate potassium/ammonium or sodium/lead(II) in the presence of other group cations. An impressive example of separation selectivity gained by the addition of 18-crown-6 to the lactate system is the complete resolution of Mg, Ca, Sr and Ba against a 1000-fold excess of sodium. Clearly seen from the electropherograms, enhanced cation selectivity can be
achieved, for example, by an addition of a suitable crown ether to carrier electrolytes.

### 3.3 Complete Complexation

Separation of metal ions in the pre-capillary-complexed form presents a viable supplementary approach of improving selectivity. Pre-capillary complexation usually leads to the formation of complete complexes with the metal ions. Since most of the metal ion is in the completely complexed state under all electrolyte conditions, manipulating selectivity is not as easy as a partial complexation. However, depending on their charge and size, the strong metal complexes can migrate towards different electrodes, so several migration modes can be applied and more flexibility with regard to the choice of separation conditions can be obtained. When complexes of metal ions with a chromogenic reagent are used, very sensitive detection can be obtained by a direct detection method. Other benefits of fully complexed metal ions are the possibility of largely reduced interferences from complex sample matrices, the feasibility of analyzing metal species incompatible with carrier electrolyte or those that possess a slow rate of complexation, and good tolerance of sample pretreatment conditions.\(^8\)

In general, the complexing reagent for complete complexation is required to be non-selective and to form a highly stable metal complex not to be dissociated in the CE system. Another requirement for complexing reagents in CE, unless the micellar-mediated CE systems are concerned, is the formation of charged complexes. To satisfy this requirement the ligand must contain at least one ionizable group, such as sulfonate, carboxylic or a quaternary ammonium group, which does not participate in complexation. A variety of complexing reagents has been previously reported. Among the most commonly used reagents, polyaminocarboxylic acids such as EDTA, CDTA and analogs appear to be most advantageous for the separation of different metal groups. These reagents are generally considered to form only 1:1 metal complexes with various metals. Even though a polydentate ligand forms very stable complexes, it can be used in the partial complexation mode if a competing ligand is added to the electrolyte to decrease the conditional stability constant of the primary ligand.\(^8\)

A number of divalent metals and Fe(III) as complexes with EDTA have been separated.\(^8\) A linear relationship between the electrophoretic mobility and the reciprocal of the square root of molecular mass of alkaline earth metal complexes has been obtained while other metals have some deviations. This was explained by differences in the degree of hydration of the complexes. CDTA has also been used for the separation of 32 divalent and higher valent metal ions.\(^8\) Among them 23 metal ions have been separated in the baseline within 10 min. Numerous high valent metal ions such as Fe(III), Sn(IV), or U(VI) have been separated. The selectivity of the separation of lanthanide complexes was studied with EDTA, CDTA and two other polyaminocarboxylic acids.\(^8\) The electrophoretic mobility of the complexed lanthanides was observed to be strongly dependent on the pH of the electrolyte. This was explained by the formation of mixed hydroxo complexes. Monodentate inorganic ligands such as cyanide or chloride are also regarded as good complexing reagents for the separation of precious metals, even though complexation conditions are difficult to control.\(^8\) Most metal complexes in this category are negatively charged. Therefore control of EOF is required for coelectroosmotic mode. More applications of complete complexation have been presented in other reviews.\(^8,9\)

### 4 MANIPULATING SENSITIVITY

A number of steps have been taken to overcome the limitations imposed by the lack of detection sensitivity of CE. Development of new sensitive detection systems is one of the most active research areas in CE in recent years. Alternative capillary geometries and improved optical design for the photometric detector is another approach toward sensitivity enhancement.\(^3\) Using commercial systems, different on-column preconcentration approaches were developed, including sample stacking,\(^9\) SPE,\(^9\) on-line ITP,\(^9\) and transient ITP.\(^9\) Among them, sample stacking is one of the most promising techniques from the practical and economical point of view. In this section, some techniques used only in environmental analysis will be introduced. Reviews of methods manipulating sensitivity have been presented in other papers.\(^2,22\)

#### 4.1 Use of Detection Cells with Extended Optical Pathlength

In commercial CE with photometric detectors, the optical pathlength for detection is limited by the narrow diameter of the capillary column due to on-column detection. To extend the optical pathlength, various special detection cells have been designed, such as Z-cells, rectangular cells, multireflection cells, along the column end cells, bubble cells, etc.\(^3\) Although these cells have enhanced sensitivity, they have also posed difficulty in manufacture and manipulation. They can even decrease separation efficiency. The bubble cell has been used in environmental analysis with an enhanced sensitivity of more than three-fold without degradation of resolution of closely migration peaks\(^9,9\) and is now commercially available.
4.2 On-column Preconcentration by Sample Stacking

Sample stacking occurs as an on-capillary concentration technique. Commonly, when the injected sample has a lower ionic strength than the running buffer, sample stacking occurs. It can also occur during the electrokinetic injection process, or separation process in case of hydrodynamic injection. Since the conductivity in the sample is lower than that of BGE, the applied voltage is not distributed uniformly along the capillary between the two ends. The field strength is higher in the sample zone, which results in higher migration velocity of an analyte ion, whereas the field strength is lower in the electrolyte, which results in lower migration velocity of the analyte ion. The analyte ion will then stack up at the stationary boundary between the two zones, thereby increasing its concentration. Sample stacking in CE was reviewed by Chien and Burgi\(^{90}\) and Song et al.\(^{91}\)

In the simplest form of sample stacking, a plug of water or low concentration buffer containing the analyte(s) is injected onto the column filled with a relatively high ionic strength run buffer. On application of a voltage of 20–30 kV across the capillary, a high electric field is developed across the sample plug which drives its ionic species towards the higher ionic strength run buffer regions. Positive species such as metal chelates and metal ions will stack at the front of the sample plug in the direction of the CZE cathode. This leads to a decrease in the LOD of order of a factor of three\(^{90}\) by the time the species has migrated to the detector. This stacking is limited to the size of the sample plug that can be injected.

A large plug of the sample can be injected. However, in this case, if the sample zone is too long, laminar flow, which originates from the different local EOF caused by the nonuniform distribution of the applied voltage, will occur and de-stack the stacked analyte ion. Therefore, the relatively large sample matrix zone during or after the stacking stage has been removed by taking advantage of EOF, which is called large volume sample stacking\(^{90,91}\). For anionic analytes, this involves field polarity reversion after the capillary is filled with sample. Then the sample matrix is pushed out of the capillary from the injection end by EOF, and anionic analytes move with a very high velocity towards the boundary between the sample and the buffer. The field polarity is switched back when the boundary is approaching the injection end of the capillary, which is indicated by the current approaching 95% of its highest value, i.e. the current when the capillary is solely filled with buffer. The LOD can then be improved by a factor of 200. The preconcentration of cationic analytes is similar, but demands a reversed EOF. However, in this approach, close monitoring of the variation on current is required for the just in time polarity switching for complete removal of the sample plug and the avoidance of sample loss. This can be solved by adding an EOF modifier, such as CTAB\(^{96}\), diethylenetriamine (DETA)\(^{92}\) or ethanolamine\(^{93}\) in the BGE to suppress the EOF, therefore the electrophoretic mobility of anions becomes higher than that of EOF.

Sample stacking can also be performed by electrokinetic injection with LOD improved by a factor of 1000; however, the reproducibility is very poor.

The reproducibility of large volume sample stacking with matrix removal as an on-column preconcentration technique was compared with that of normal injection,\(^{97}\) giving a result of typically 4.0 vs 1.2% for peak area and no differences for migration time. It was indicated that this preconcentration technique requires samples having a relatively low and reproducible conductivity.

In normal sample stacking with hydrodynamic injection, the ionic strength of samples has a significant effect on sensitivity.\(^{98,99}\) Higher ionic strength of a sample led to lower LOD. Recently, large volume sample stacking with matrix removal has been applied to the analysis of small organic and inorganic anions without polarity switching.\(^{100}\) The pH is adjusted to the acidic range so that the EOF can be adjusted to be slower than the electrophoretic mobilities of small anions and more than 300-fold enrichment was readily achieved. In the analysis of methylmercury, the achieved LOD was 12 ppb with large volume sample stacking with matrix removal.\(^{101}\)

Sample stacking can also be used in MEKC. For ionic analytes, the procedure is the same as in CZE. However, for neutral analytes the procedure has to be modified a little. Liu et al.\(^{102}\) reported the accomplishment of sample stacking of neutral analytes by dissolving them in a micellar solution with a low concentration just above critical micelle concentration (CMC). The micelles were stacked up under applied voltage, and caused stacking of neutral analytes. Normal and reversed field polarity was used and produced a 75–85-fold increase in sensitivity for 1,2,4,7- and 1,2,4,8-tetrachlorodibenzo-p-dioxin (TCDD). Susse and Muller\(^{103}\) used sample stacking with reversed field polarity as an on-column preconcentration technique for the analysis of pesticides by MEKC. LODs between 0.01 and 0.1 ppb were achieved, where 30-fold preconcentration was attributed to sample stacking and 250-fold to SPE.

4.3 On-line Preconcentration by Isotachophoresis

ITP can be used as a preconcentration technique for diluted samples in CE. In this procedure a small quantity of the sample is introduced at the interface of a discontinuous buffer system, consisting of a leading and a terminating electrolyte. The analyte ions migrate between a leading ion having the highest mobility and a terminating ion having the lowest mobility in the
buffer system. Under applied voltage, the analyte ions stack up and migrate as consecutive zones, according to their mobility between the leading and terminating ions. Establishing ITP conditions at the beginning of a run provides a method for on-column preconcentration; separation then proceeds by zone electrophoresis. From the point of view of trace analysis, ITP can be considered a good preconcentration technique for CE but coupling ITP and CE instrumentation can be rather complex. Recently, ITP coupled with CZE has been shown to be capable of being performed in a single capillary by taking advantage of a countercflow. Moreover, ITP can also be performed before CZE separation as a transient preconcentration step (ITTP) in commercial CE instruments by carefully selecting the CZE electrolyte as a leading or terminating electrolyte to form an ITP buffer system with an additional electrolyte. There is a review on these two techniques.  

4.4 Preconcentration by Solid Phase Extraction

SPE inside the capillary is another preconcentration technique capable of providing a concentration factor of 10–10^5, effective especially for aqueous samples. This solid phase can be incorporated as a short plug at the beginning of the capillary, or as a hydrophobic stationary phase bonded to the inner wall such as an on-line coupled C_{18}-coated column. However, in the latter case, because of the low amount of the wall-coated stationary phase, the enrichment factors were limited to 10–35-fold. When in-column SPE is applied, the sample must be cleaned before it is introduced into the capillary and cannot be introduced directly because of the risk of blocking the system.

4.5 Use of Alternative Detection Techniques

To improve the detection sensitivity of CE, a range of other detectors has been developed. Among them, indirect LIF, CL, ED and ICPMS received much attention as popular choices for high-sensitivity detection of inorganic ions. The advantages, disadvantages and limitations of each technique are presented in section 2.3.

5 APPLICATIONS

This section will give a general overview of CE procedures suitable for practical application. Therefore, some selected results of both basic and applied research will be presented. The following is divided into sections dealing with metal cations, metal speciation, inorganic anions and simultaneous determinations of cations and anions.

5.1 Determination of Metal Cations

The main strategy for the simultaneous determination of metal cations by CE is complexation. Many metal cations have nearly identical charges and identical hydrated ionic radii. Therefore, all complexations, whether weak, strong or inclusive, need to be applied for proper separations.

The most significant agent is HIBA, widely used for the separation of alkali, alkaline earth metals, transition metals, and lanthanide. Using the on-capillary complexation principle, separation of 19 cations in only a few minutes has been accomplished as shown in Figure 2. A quinine sulfate buffer system with HIBA has been used for the indirect fluorescence detection of several alkali and alkaline earth metals. Reagents such as HQS and 1,10-phenanthroline have been employed for the quantification of zinc(II) and iron(III), respectively, in tap water samples without preconcentration. The latter can lead to a loss of analyte and peak broadening. There have been several examples indicating that this complexation technique makes it possible to reduce interference from complex sample matrices (electroplating solutions, ores, catalysts, ceramics, etc.).

Complete complexation with pre-capillary mode has been applied for the separation of a number of alkali and alkaline earth metal ions. EDTA was used as a complexing reagent and pyridine as UV chromophore for indirect UV detection. CDTA also was used for the separation of lanthanides as anionic complex.

For the determination of precious metals, complexation with chlorine or cyanide is a popular method, even though more rigid control of complexation conditions is required. Os(IV), Pt(IV), Ir(III), Pd(II), Au(III), and Rh(III) were separated efficiently within 5–6 min as chloro complexes with detection limits of 0.1–0.6 ppm.

Enhanced selectivity for alkali and alkaline earth metals can also be obtained with a suitable macrocyclic polyether (like crown ethers) incorporated into the electrolyte. As an additional separation mechanism with complexation function, stronger complexing reagents, e.g. EDTA, but under conditions of incomplete complexation, are of certain use to manipulate differences in effective mobilities of alkaline earths and magnesium as well. The more interested reader should refer to the reviews listing the experimental conditions of determination of metal ions by CE from almost all publications before 1997.

5.2 Metal Speciation

The ability to resolve different oxidation states of a metal is a distinct benefit of CE. Since it causes a minor disturbance on the existing equilibrium between different species, CE gives a unique promise for speciation purposes. Most of the studies performed on speciation...
have been focused on the optimization of separation parameters in order to separate various metal species in environmental, biological, and industrial samples. Since a recent review has been published, some recent examples of the application of CE to the metal speciation will be presented in this section.

Complexation is the most valuable approach for performing metal speciation on different oxidation states. Separations of metal ions in a free, uncomplexed form are comparatively rare in the practice of CE for metal speciation. Complete conversion of metals to charged complexes, which takes place upon the addition of a complex reagent to a sample before introducing to a capillary, yields differences in charge densities while the initial concentration ratio of different oxidation states is preserved. For speciation involving metal oxidation forms of opposite charges, pre-capillary complexation is a straightforward strategy to impart the same charge and electrophoretic direction on the species.

Among the numerous metal cations that exhibit toxic effects on humans and plants or aquatic organisms, the most frequently studied ones are aluminum, iron, copper, manganese, nickel, and zinc. Inorganic Al(III) and its complex forms appear to be much more toxic than organically bound aluminum. To study the distribution of aluminum and its inorganic and organic complexes in aqueous solutions by CE, indirect UV detection was performed with imidazole as a UV-absorbing component of the electrolyte. Good resolution was obtained for the analysis of a sample solution containing four aluminum species: Al\(^{3+}\), AlF\(^{2+}\), AlF\(^{3+}\), and Al (oxalate)\(^+\) during a period of less than 5 min. As a certain disadvantage for practical purposes, high detection limits (10 \(\mu\)M) shall be noted; these are of 1–2 orders of magnitude above those needed for use in natural waters. With CE separation of Fe(II) and Fe(III) ions the major problem is the selection of complexing agents suitable for the derivatization of both iron species. There are some reports which show the possibility of separating the Fe(II) and Fe(III) ions by CE after pre-capillary complexation with EDTA and CDTA.

The utility of micellar-mediated CE to differentiate Fe(II) and Fe(III) following derivatization with 4-(2-pyridylazo)resorcinol (PAR) was reported. The limits of detection accomplished in the visible spectral region (500 nm) were in the submicromolar range. Later, in an attempt to enhance the sensitivity, on-column complexation with PAR, in combination with sample stacking as an enrichment step, provided a 100-fold improvement in the detection limit for iron(II) over the precolumn complexation method. This allowed the authors to apply the procedure to the development of the analysis of a pond water sample. Iron species, while they are stable in the carrier electrolyte solution, can be determined without derivatization by means of an element-specific detector such as inductively coupled plasma atomic emission spectroscopy (ICP AES) or ICPMS, as was demonstrated by Olesik et al. Since the analytes exist in a highly mobile cationic form in this case, an analysis time of 1 min or less is attainable. Furthermore, separation of different metal ions from each other was not needed due to the high selectivity of ICP spectrometry.

There is a continuing interest in the determination of chromate ion, the most toxic of chromium species, motivated by the fact that chromium is commonly used in various industries and a considerable amount may be released into the environment. The first successful speciation of both oxidation states of chromium through CE separation was achieved by converting Cr(III) into a negatively charged complex with CDTA in order to impart the same charge and similar mobility to chromium species. The separated anionic species were monitored by direct UV measurements at 214 nm. The procedure was applied to rinse water and processing solution samples and was found to be free of interference from transition metal impurities. Similar results have been obtained with EDTA instead of CDTA for the separation of the Cr(III) and Cr(VI) species by Jung et al. with the same separation strategy.
Speciation of arsenic is of particular interest because of the wide range of toxicity exhibited by the different chemical forms. CE has been widely used for the separation of arsenic compounds. Direct UV absorption detection at a wavelength between 190 and 200 nm is the most commonly employed. However, the arsenic concentrations to be detected are generally at ppm levels in aqueous solutions. Therefore on-column preconcentration such as field amplified injection has been applied or coupling of CE with ICPMS has been actively developed.

Selenium can be a toxic or an essential element depending on its chemical state. Several studies have focused on applying CE for the separation of selenium species using various electrolyte composition and detectors. For the speciation of oxoanions of selenium, or arsenic, the coelectroosmotic migration mode by reversing the direction of EOF towards the anode is suitable for resolving oxoanions and organic anionic forms of selenium. Counterelectroosmotic migration modes have also been applied for the speciation of oxoanions of arsenic, where variations of the electrolyte pH offer an effective means for separation efficiency control over metal oxoanions. As anions of polybasic acids, these species are pH-sensitive and show a strong dependence of ionic mobility on the carrier electrolyte acidity. The anionic analytes can be transported towards the cathode by the EOF, if their charge is reduced by using slightly acidic or neutral buffers. This combination of cathodic EOF and detection is favorable for the separation of arsenic compounds. If the electrophoretic mobilities of oxoanions are greater than that of EOF, they can migrate counterelectroosmotically towards the anode. This is the case for arsenates and selenates which exist as doubly-charged anions over a wide pH range. For their fast separation from the slowly migrating arsenite and selenite species, the pH of the electrolytes should be higher than 10 where all anions are essentially ionized. To shorten the separation time further, an EOF modifier like a cationic surfactant can be incorporated into the electrophoretic buffer in order to suppress or reverse EOF.

In practice, however, applications of the procedures developed to date are rather scanty, evoking problems with real sample matrices. Few exceptions deal with the analysis of waters and soil extracts, coal fly ash, water samples from a tailing of tin mine processing, spiked water and urine samples. The toxicity of many organometallics often exceeds that of the same metal inorganic species, which makes the speciation of paramount importance. Separation of cationic organomercurials and inorganic mercury(II), facilitated by the formation of their complexes with cysteine, was examined by Medina et al. For methylmercury, which is recognized as one of the most dangerous chemical species in the environment, direct UV detection of the cysteine complex provided a detection limit as low as 10 pg. The CE procedure developed has proved to be efficient for rapid and simple determination of methylmercury (at the level of low ppb) in biological materials of marine origin. CH$_3$Hg$^+$ was extracted from the sample (as chloride derivative) with toluene, then back-extracted with a 0.1% cysteine solution and, finally, the aqueous extract was subjected to CE analysis. A unique possibility of MEKC to separate both neutral and charged analytes was exploited for simultaneous separation of organoselenium and organolead compounds. The complete resolution of a test mixture of trialkyllead and phenylselenium compounds has been accomplished. The competitive interactions of the analytes with electrolyte components, sodium dodecyl sulfate and β-cyclodextrin, taking place via hydrophobic and host–guest complexation mechanism, respectively, appear to govern the migration pattern observed. For organotin species, the migration behavior in MEKC was found to be dominated by the distribution ratios of the solutes between the aqueous electrophoretic and micellar phase, i.e. by their hydrophobicity.

Note that a majority of the reports involving water or biological matrices have only demonstrated the analysis of spiked samples, as for many metalloorganic contaminants the concentration levels in these objects are beyond the detection sensitivity of CE analysis. For example, Ng et al. developed a scheme for the determination of trimethyl- and triethyllead, which includes preconcentration by means of liquid–liquid extraction and evaporation and then MEKC. However, the compounds under investigation were not even detected in a water sample collected at a heavily used car park, since they were present at levels below the detection limits. Neither allowed the enrichment by more advantageous membrane SPE on a C$_{18}$ disk to determine organolead and organotin species in non-spiked water samples using MEKC. A combination of subcritical fluid extraction, using chlorodifluoromethane as solvent, and MEKC has been applied for the determination of alkyllead and alkyltin compounds in solid samples. To improve the recoveries of two less hydrophobic trimethyl species, sodium diethyldithiocarbamate was added as a complexing agent to the soil sample before extraction. However, direct analysis was only possible for a rather high content of dibutyltin stabilizer (1.2–1.5%) in poly(vinyl chloride) plastic.

5.3 Inorganic Anion Analysis

The determination of common inorganic anions such as fluoride, chloride, bromide, nitrite, nitrate, phosphate,
and sulfate, is a significant factor in the characterization of the quality and the extent of contamination of water. Since they do not have enough chromophoric characteristics and the direction of electrophoretic mobility of anions is opposite to that of EOF, in determining them by CE with untreated fused silica capillaries, the common procedure includes a reverse of EOF from cathode to anode and indirect detection. Many of studies performed have been focused on the optimization of separation parameters of electrolyte based on above two strategies.\(^{140–150}\) Jandik and Jones systematically developed the separation procedure for anion analysis\(^{3,25}\) and accomplished spectacular separations of inorganic anions, as well as small organic anions in a very short time. CE has been applied to the anion analysis of a variety of environmental samples, such as natural water\(^{151}\) drinking water\(^{152}\) tap water, water from the space shuttle and space station\(^{153}\) wastewater\(^{154}\) seawater,\(^{155}\) soil solution,\(^{133,156}\) silicon product,\(^{157,158}\) toothpaste,\(^{159,160}\) single rain, fog, and cloud drops,\(^{161}\) aerosols\(^{151}\) etc. A specially developed sampling procedure has been applied in the analysis of a single rain, fog, or cloud drop. This shows that CE can be applied to the quantitative, multicomponent chemical analysis of ultrasmall volumes, like a single rain or fog drop. CE has been compared with IC in anion analysis.\(^{153,158,162,163}\) It was reported that CE has been proved to be a good alternative to IC since it gives usually good agreement with IC in their results even though their detection limit is usually a little inferior to IC. A comparison for the results of CE and IC is shown in Figure 4.

Speciation of sulfur, nitrogen, or chlorine in various water samples has been performed.\(^{164–166}\) Numerous chlorine-containing anions with different oxidation states, such as chloride, chlorite, chlorate, and perchlorate in tap water, swimming pool water, and bleaching preparation were separated by CE and IC.\(^{1160}\) CE has advantages for the quantitative determination of chlorine-containing anions in several hundreds ppb level in the presence of a large excess of chloride or nitrate and sulfate.

### 5.4 Simultaneous Determination of Cations and Anions

A simultaneous determination of inorganic cations and anions in a single analysis is both advantageous and necessary. However, no specific technique is available for this purpose up to now. CE can be developed for simultaneous determination of cations and anions but it still remains a challenging problem. Cations and anions were usually separated using different BGEs under different conditions in CE. Following are some reports about the simultaneous determination of cations and anions. A common strategy among them is taking dual electrolyte for indirect detection of cation and anion and finding the optimum EOF.

A simultaneous determination of small cations and anions has been performed in one single electrophoretic run using one capillary and one detector.\(^{167}\) In this

Chem.*, 70, 360–365 © 1998, with permission of the American Chemical Society.)
case the sample is injected into the one end of the capillary and subsequently into the other end of the capillary. Cations and anions migrate against each other toward the center of the capillary where the detection window is placed. 4-Aminopyridine and chromate with CTAB have been used as electrolytes. 22 small inorganic and organic anions and alkaline and alkaline earth metal cations were separated within 5 min as shown in Figure 5. Adapting the same sample injection strategy with different electrolyte composition, chloride, sulfate, hydrogen carbonate, potassium, ammonium, calcium, sodium and magnesium ions were simultaneously separated.\textsuperscript{188} Two electrolyte systems based on imidazole-nitrate and copper(II)-ethylenediamine-nitrate have been applied for indirect UV detection at 214 nm.

Introducing an ion-exchange electrokinetic chromatography mechanism, simple simultaneous determination of inorganic anions and kinetically stable metal-PAR chelates has been obtained.\textsuperscript{143} The addition of cationic polymers to the background electrolyte reverses EOF and decreases electrophoretic mobility of anions according to their abilities to associate with polymeric cations. Chromate was chosen as a background electrolyte anion because it enables indirect UV detection of transparent anions at 254 nm and does not affect the direct detection sensitivity of chelates at 490 nm. Rapid (4 min) separation of Co(II), Ni(II) and Fe(II)-PAR chelates and of 11 inorganic anions was obtained.

Benzylamine, imidazole, benzenesulfonic acid, sulfosalicylic acid, and pyromellitic acid were tested as the components of the BGE for simultaneous separation of cations and anions.\textsuperscript{169} The electrolyte components and control of the migration velocity were found to be the main factors for the separation.

6 CONCLUSIONS AND FUTURE TRENDS

As discussed in the previous sections, CE is an analytical separation technique that has great potential for environmental analyses. This is reflected in the rapidly increasing number of publications on CE. A diversity of inorganic species in real samples has already been proved to be amenable to the analysis by CE, and more can be expected in the years ahead. CE procedures provide high separation efficiency and high-speed separation, and are simple enough to be used on a routine basis. In application, however, limitations imposed by the lack of detection sensitivity complicate the technique’s use and impede its wide acceptance. To overcome sensitivity problems in the determination of metal ions, the coupling of CE with ICPMS is now being attempted. This is done as an alternative to the two research techniques competing with each other. By doing this, not only the sensitive determination of elements but also particular speciation information of each element can be obtained. Interface design, however, is still being developed.

The advantages of CE compared to IC are speed, resolution, and the lack of a need for gradient elution. Operating costs are considerably lower, since ion-exchange columns are usually expensive. However, when a comparison on the data was made, the precision, linearity, and concentration LOD of CE were usually inferior to those of IC for the same analysis.\textsuperscript{170} However, CE has the capability of analysis in three different areas:

1. analysis in complex matrices,
2. simultaneous determination of inorganic and organic pollutants and
3. metal speciation with simple pretreatment of sample and simple procedure.

As such, this technique remains as a complementary technique for IC or HPLC.

Another future of CE is in creating a miniaturized (or micro-) total analysis system. CE contains the qualities of speed, sensitivity, and small sample volumes that are desirable for a micro-total analysis system.\textsuperscript{170} Using microlithography on glass structures, CE has been carried out on a chip. These chips allow for low sample volumes, fast analysis times and good separation efficiencies and has a possibility to be developed for a portable system that would be particularly useful in field analysis of environmental samples.

After the industrial revolution considerable emphasis was placed on monitoring organic, inorganic and organometallic substances in the environment. Environmental contaminants include products of combustion, vapors, gases, industrial solvents, dusts, agricultural fertilizers, pesticides, radioisotopes, noise, ultraviolet light and certain microwave electromagnetic radiations.

Contaminants that are present in strong enough concentrations to pose an immediate threat to life or to cause unmistakable cases of disease or acute poisoning are usually readily apparent, and experience has led to the development of adequate, but by no means perfect, environmental control measures. The effects of environmental contaminants are related to time as well as concentration or intensity. Time factors become increasingly important when low concentrations of contaminants do not produce ill effects until after months or years of exposure. Trace analytical methods, therefore, play a very important role in environmental analyses. They are required for the detection and identification of chemical pollutants present in the environment. It is essential that the analytical methods applied are suitable and that they yield reliable data. These methods have to have high sensitivity, as many toxic chemicals are present in environmental samples at microgram per liter levels. Furthermore they have to cover a large dynamic range, and most important they have to be inexpensive. Voltammetry fulfills all of these features and it can be used both in trace metal analyses and in the determination of organic compounds in environmental samples. This article will cover the determination of inorganic pollutants in air, water and soil, using electrochemical (EC) methods.

1 INTRODUCTION

In recent years considerable emphasis has been placed on monitoring chemical pollutants in the environment. Most people are exposed to a large number of chemicals emitted from different sources. This increased exposure is viewed, by some, as an inevitable side effect of technological advancement. For example, the inhabitants of cities are exposed to large concentrations of lead caused by the combustion of leaded petrol in cars. Although many countries have taken measures to prevent the accumulation of lead in the atmosphere, soils, waters, and so on, by abolishing or restricting the use of tetraethyllead as a gasoline additive, developing countries still suffer from a steady increase in lead levels. Even at relatively low concentrations, lead acts as a metabolic poison and accumulates in bones by replacing calcium. It inhibits the enzymes needed for the synthesis of hemoglobin owing to its strong interaction with SH groups. One of the toxic manifestations associated with an increase of lead level in the body in young children is a reduction in their learning ability. Despite this knowledge, it is only in the recent past that there has been any attempt to reduce the concentration of lead in petrol.

The contamination of the environment is widespread. Nriagu and Pacyna\(^{1}\) have presented a worldwide inventory of industrial and municipal discharge of metals into soils and the aquatic ecosystem. The annual discharge exceeds the combined output of all radioactive and organic wastes generated each year as measured by the amount of water needed to dilute such wastes to drinking water standards. One of the important features that distinguishes metals from other pollutants is that they are not biodegradable. Once they have entered the environment, their potential toxicity is controlled to a large extent by their chemical form.
Toxic metals, such as Cd, Cu, Ni, Pb, Zn, and so on, and acid rain contribute substantially to the pollution of land and waters and cause increasing damage to the various components of both, especially forests. Determination of these ions in wood samples using inverse differential pulse (DP) voltammetry showed that Pb and Cd concentrations were higher in wood from polluted regions than in nonpolluted regions. The difference between natural changes and the effects of industrial development during the last 100 years is the amount and speed of alteration, which deprives the biological systems of any chance of adapting, albeit slowly, to the newly created conditions. Today the average adult human body contains about 10 times the amount of lead found in mummified Egyptian bodies.

Increasing environmental pollution by toxic metals and also by organometallic and organic pollutants calls for reliable analytical procedures for their control in air, water and in soil. There has been an increasing public awareness of the dangers of exposure to toxic substances. Obviously there is a need to control and manage the environmental burden caused by “chemical pollutants”. Hence research to ascertain the levels and pathways of these environmental pollutants has become more important. Trace analytical methods play a very important role in environmental analysis. They are required for the detection and identification of “chemical pollutants” present in the environment. Trace analytical determinations, subsequent to sampling and sample preparation steps, are usually carried out using instrumental methods. However, in order to be suitable for trace analysis, these methods must fulfill certain basic requirements. They need to have high sensitivity, as many toxic chemicals are present in environmental samples at microgram per liter levels. Furthermore, the dynamic range should be large, covering a concentration range typically from several hundred microgram per liter down to microgram or even picogram per liter levels. In situations where environmental levels of hazardous chemicals are to be established, an extension of the detection limit down to nanogram concentrations is essential. A further requirement of any instrumental method is that it has the necessary selectivity to deal with the problem in hand. The most important consideration in trace analysis is accuracy; that is, the closeness of agreement between the observed result and the known or true value. There now exist a large number of instrumental methods, but not all incorporate the aforementioned requirements. Among the most suitable are the EC methods of polarography and voltammetry. Voltammetry in particular has proved its usefulness both in the fields of trace metal analysis and in the determination of organic compounds in environmental samples.

2 ELECTROCHEMICAL METHODS

For environmental analysis, like every other kind of analysis, the need is for simple, reliable and viable techniques. Analyses are costly, and running costs particularly can be very high. The task of the analytical chemist is to choose the most appropriate procedure in order that the desired information about the particular material of interest can be provided. Next to advanced electroanalytical techniques, modern atomic absorption spectrometry (AAS), inductively coupled plasma atomic emission spectrometric and inductively coupled plasma mass spectrometric methods are commonly used in industrial, technical and control laboratories. Neutron activation analysis (NAA) is a powerful detection method but costly both in terms of investment and operation expenditure. The features that make electroanalytical methods competitive techniques are the very large useful concentration range ($1 \times 10^{-10}$ M), the larger linear ranges available in many commonly used instrumental techniques, the ability to assay dissolved and solid samples, the ability to speculate on the basis of complex liability and to distinguish between different states of valency, and the immunity of the matrix to samples with high ionic content, and so on. Perhaps the most important point with respect to environmental analysis is that polarography and voltammetry are among the very few techniques that are equally suitable for analysis of inorganic, organometallic and organic compounds to concentrations below $10^{-9} - 10^{-10}$ M, and surfactants using tensammetric techniques. Inductively coupled plasma mass spectrometry (ICPMS), for example, has a limited capability for the determination of organic pollutants. Modern electroanalytical methods are applicable to all toxic metals and metalloids of environmental and toxicological relevance. Metals of particular importance in freshwaters that can be easily determined by EC techniques are Cd, Cr, Cu, Hg, Ni, Pb and Zn.

Polarography and voltammetry rank today as low-cost techniques. The instrumental costs, degree of automation and the time required per determination are related in a complex way to the economics of the laboratory. Costs and expertise virtually exclude installation of an ICPMS system in a smaller routine laboratory. If the prices for purchase are compared (ICPMS costs 400 000–600 000 DM, AAS costs 25 000–150 000 DM, polarography and voltammetry cost 10 000–50 000 DM), it is clear that voltammetric instruments are much cheaper. The operating costs are very high for ICPMS due to the large amounts of Ar (13–18 L min$^{-1}$) consumed; the costs are medium for AAS but again very low for voltammetric analyses.

Polarography and voltammetry are well-known EC methods which can be used to study solution composition through current–potential relationship. Polarography is
the branch of voltammetry that is used to investigate solution composition by the reduction or oxidation of ions or molecules at a dropping mercury electrode (DME) under the influence of an applied potential. Direct current (DC) polarography involves measurement of the current variation at a DME as the applied potential ramp is linearly changed with time. As a result of the charging current at the DME a significant background current is observed, which limits the sensitivity of DC polarography to concentrations in the \(100 \mu \text{g L}^{-1}\) region.

An increase in the ratio of faradaic current to charging current has been accomplished by pulse polarography. One of the most widely used pulse modes in trace analysis is DP polarography. In this mode, small potential pulses are superimposed over a conventional DC voltage ramp and applied to the DME near the end of the drop lifetime. The current is sampled just before application of the pulse and again at the pulse when the charging current has decayed. It is the difference between these two current measurements that is displayed. Hence the ability of DP polarography to discriminate against the charging current lowers its limit of detection over DC polarography. Because DP polarography is an extremely sensitive method, it is applicable to both inorganic and organic analysis, yielding peaks for concentrations in the microgram per liter to milligram per liter range.

There are at least three types of catalytic current which should not be intermixed:

1. Catalytic reduction of hydrogen ions caused by a decrease in overpotential, resulting usually from interaction of hydrogen ions or other proton donors with the oxidized or reduced form of a catalyst adsorbed at the electrode surface. Numerous organic compounds containing sulfur or nitrogen (both acyclic and heterocyclic) are examples of such catalysts.

2. Catalysis of hydrogen evolution by platinum group metals, either in the solution or at the electrode surface.

3. Catalytic currents caused by a homogeneous chemical reaction, e.g. to a reoxidation of a metal ion, reduced electrochemically to a lower oxidation state. Such catalytic currents increase with increased concentration of the oxidizing agent and were observed in particular in the presence of Fe(III)/Fe(II) and Ti(IV)/Ti(III) couples as well as some complexes of Mo(VI) and Mo(V).

To increase the sensitivity above that offered by pulse and square-wave techniques, an accumulation of the species to be determined at the electrode surface is carried out. For this purpose voltammetric methods such as anodic stripping voltammetry (ASV), cathodic stripping voltammetry (CSV) or adsorptive stripping voltammetry (ADSV) employ stationary mercury electrodes or solid electrodes such as glassy carbon or gold. These methods are among the most sensitive voltammetric methods used in environmental analysis. Stripping voltammetry involves two steps. In the first step, the analytical species of interest are deposited either as amalgams, as mercury salts or as adsorbates onto a stationary electrode such as a hanging mercury drop electrode (HMDE) or mercury film electrode (MFE). The time required for the deposition step depends on the concentration of the analyte present. It is important that the conditions used in the deposition step, such as deposition potential, deposition time and stirring rate, are strictly controlled to ensure reproducible results. The second step involves stripping the deposited species from the electrode back into solution. The most commonly used waveforms in the stripping step are the linear sweep and DP modes. The DP waveform has become more popular because it is more effective in discriminating against charging currents and permits lower detection limits. The magnitude of the stripping current is proportional over a certain range of concentrations and deposition times to the concentration of the species of interest.

So far, stripping voltammetry has proved to be a very useful technique in the determination at the subnanomolar concentration level of some 25 metals that deposit electrolytically and form stable amalgams with mercury. However, some heavy metals, i.e. Ni, Co, and Ti, do not possess these properties and, consequently, cannot be determined by conventional stripping voltammetry. Their determination has then been accomplished by ADSV. In this technique, the preconcentration step is carried out by adsorbing a metal chelate at the surface of the electrode. The reduction current of either the metal ion or the ligand in the adsorbed complex is used to quantitate the surface bound species and this current is directly related to the metal concentration in the bulk of the solution. Since most metal–chelate complexes have a hydrophobic nature and show a marked tendency to adsorb onto the mercury electrode, this preconcentration scheme does not necessarily require that a preconcentration potential be applied to the electrode. This fact enables the avoidance of many interferences caused by electroactive impurities present in the sample. On the other hand, the presence of surfactants should be avoided for they might compete for the adsorption sites of the electrode, thus decreasing the stripping signal. ADSV has been applied to the simultaneous determination of Ni and Co in a variety of real samples including plants, fruits, body fluids and rainwater, using dimethylglyoxime (DMG) as chelator. Samples are adjusted to pH 9.2 with ammonia buffer followed by addition of DMG. A potential of
$-0.7 \text{ V}$ is then applied to the working electrode while the solution is stirred for several minutes. Subsequently, the adsorbed Ni(DMG)$_2$ and Co(DMG)$_2$ are reduced by scanning the potential in the negative direction. ASV could also be applied for the determination of selenium(IV) by using the adsorptive properties of selenium–TGA (thioglycolic acid) complex in 4 M HCl. Here, the deposition was carried out for 2 min at $-0.1 \text{ V}$ and the response was recorded by scanning the potential from $-0.1$ to $-0.7 \text{ V}$. A reduction peak at $-0.46 \text{ V}$ was observed and $2 \times 10^{-8} \text{ M Se(IV)}$ could be determined. Linear scan voltammetry can be applied to analyte concentrations of 1 $\mu\text{g L}^{-1}$, whereas the DP mode is used for concentrations down to 1 ng L$^{-1}$. The sensitivity of ADSV is greatly enhanced by the fact that the stripping step proceeds from the adsorbed layer rather than from the whole of the electrode. For this reason the use of this technique has been extended to the analysis of metals that traditionally had been determined by ASV.

In stripping voltammetry, the sensitivity of the method depends very much on the type of working electrode used. An HMDE may be used for the analysis of trace metals down to several micrograms per liter, an MFE on the other hand may be employed for even lower concentrations.

When mercury electrodes are used in ASV, about 20 amalgam-forming metals may be determined. By contrast, metal ions such as selenium, tellurium, arsenic, mercury and silver may be determined using solid electrodes such as the glassy carbon electrode (GCE) or gold. A chemically modified GCE in conjunction with differential pulse anodic stripping voltammetry (DPASV) has been used to measure Cu at concentrations as low as 100 ng L$^{-1}$ in laboratory prepared solutions. The properties of the dialysis membrane and the advantages of the MFE have been brought together in a rotating glassy carbon membrane covered MFE. The use of this electrode enabled detection of 97 ng L$^{-1}$ of Cd in aqueous solutions when the DPASV mode was employed, the response being linear over three orders of magnitude.

Carbon paste chemically modified electrodes are very simple to prepare and have been used to determine Ni(II) in a variety of reference materials, including water, coals and sediments. Here Ni(II) was chemically deposited on the modified electrode and the DP voltammetric determination was carried out after transferring the electrode to a separate buffer. After a 240-s preconcentration period, up to 0.050 $\mu\text{M Ni}$ could be detected. A novel strategy for electrode modification has been the incorporation of a microorganism as a modifier in a carbon paste electrode. The common brown alga shows a strong affinity towards copper and advantage was taken of this fact to bioaccumulate Cu(II). A further example is the development of a gold film microelectrode formed by plasma-sputtering gold onto carbon fibers. This electrode has been used for the detection of mercury using DPASV, with a detection limit of 3.7 $\mu\text{g L}^{-1}$.

Catalytic polarography is used also for increasing the sensitivity of the measurement. The catalytic current is frequently much greater than the diffusion current. It may be used in different situations, such as catalytic cathodic stripping, catalytic ADSV, catalytic current polarography or catalytic hydrogen wave polarography.

Reviews of the environmental determination of inorganic species include fluoride, organometallic compounds, and total arsenic and arsenic compounds using EC methods. Some inorganic methods included advanced electroanalytical techniques and EC sensors. The application of various electroanalytical techniques to environmental analysis has been reviewed. The various techniques used include chronopotentiometric stripping, voltammetry, and polarography. Many reviews on the environmental occurrence, properties, and determination of specific analytes have also been published. Voluminous reviews on environmentally significant metals have appeared in three volumes. Other reviews have appeared on the electroanalytical determination of inorganic species in the environment and the chromatographic analysis of metals, mercury and its compounds, arsenic species, organolead compounds, cadmium, and sulfur compounds.

### 3 AIR ANALYSIS

The atmosphere is a protective blanket for the continuation of life on the earth; it is the source of carbon dioxide for plant photosynthesis and of oxygen for respiration. It provides the nitrogen that nitrogen-fixing bacteria and ammonia-manufacturing plants use to produce chemically bound nitrogen, an essential component of life molecules. As a basic part of the hydrological cycle the atmosphere transports water from the oceans to land. Unfortunately, the atmosphere has also been used as a dumping ground for many pollutant materials, ranging from sulfur dioxide to the refrigerant Freon which causes damage to vegetation and materials, shortens human life, and alters the characteristics of the atmosphere itself. The atmosphere absorbs most of the cosmic rays from outer space and protects organisms from their effect.

Protection of public health has long been an important force for the control of air pollution, beginning with the dramatic increases in daily deaths during the episodes of severe air pollution between 1930 and the early 1960s. Early measurements of air pollution in cities focused on two pollutants: sulfur dioxide and particulate matter. Present-day air quality control recognizes several
additional pollutants as potentially important to health, including oxidants and ozone, carbon monoxide, nitrogen oxides, lead, organics such as formaldehyde, and various aerosol constituents. Atmospheric aerosols are solid or liquid particles smaller than 100 µm in diameter. Pollutant particles in the 0.001–10-µm range are commonly suspended in the air near sources of pollution, such as the urban atmosphere, industrial plants, highways, and power plants. For the most part, aerosols consist of carbonaceous material, metal oxides and glasses, dissolved ionic species (electrolytes), and ionic solids. Some of the metals found predominantly as particulate matter in polluted atmospheres are known to be hazardous to human health. All of these except beryllium are so-called “heavy metals”. Lead is the toxic metal of greatest concern in the urban atmosphere because it comes closest to being present at a toxic level; mercury ranks second. Others include beryllium, cadmium, chromium, vanadium, nickel, and arsenic.

3.1 Reviews and Monographs

A monograph covers several aspects of aerosol characterization. The application of several microanalytical techniques for characterization of individual environmental particles has also been discussed.

Stanley-Wood and Lines edited a book on particle size analysis. Smoley authored a text on methods of determining metals in environmental samples. Merian published a review on the occurrence, analysis, and biological significance of metals in the environment. Other reviews dealt with electroanalytical methods for Zn, Cd, Se, and As, procedures for determination of arsenic, and determination of cadmium in biological and environmental samples.

There are many reviews of analysis of atmospheric environmental samples ranging over seven major subcategories including sample collection, radon measurements, airborne microorganisms, site-specific assessments, methods of analysis, field instrumentation, and composition of aerosols.

The subject of collecting samples of air was reviewed with respect to particulate sampling technology, consideration of sampling specifics for compliance to USOSHA (United States Occupational Safety and Health Administration) standards, and sampling indoor atmospheres in workplace air monitoring. Substantial interest has been shown in actual methods of analysis for indoor air monitoring of environmental carcinogens, organic vapors, and tracer gases for ventilation studies. Noteworthy reviews from India and from China were used to describe modern instrumental methods of atmospheric pollution analysis for toxic compounds. Extensive coverage has been given to reviews of aerosols. Especially relevant here is the review of chemical composition of aerosols and trace elements in indoor/outdoor dust.

Air monitoring is a global concern as shown by reviews of air pollution determination by gaseous and particulate sampling methods, the state of environmental analytical chemistry and pollution climates in Europe, and the monitoring of atmospheric pollutants from space. Various combinations of filter media, extraction and analysis techniques used in the determination of inorganic species have been compared.

3.2 Sample Collection

Sample collection is probably the most important step in trace analysis. Meaningful results will only be obtained if all risks of contamination are either minimized or eliminated. This, however is not an easy task.

Sampling of airborne matter was the topic of a review. The use of diffusive samplers to assess community air pollution problems was also discussed.

Kasahara et al. described the optimum sampling conditions for analysis of atmospheric aerosols by particle-induced X-ray emission (PIXE) methods. In order to obtain time resolution for aerosol composition, samplers have been developed that can deposit aerosol particles at different locations on the collection surface. These samplers are referred to as streakers. PIXE has sufficient sensitivity to be able to analyze a small quantity of deposited aerosol and PIXE multielement analysis has been applied to aerosol characterization in Milan, Hungary, and with cascade impactor sampling in Vienna. In one work air samples from Ankara were collected on glass-fiber filters and were analyzed by differential pulse polarography (DPP).

3.3 Techniques

DPP has been successfully applied to the determination of copper, lead, cadmium, zinc and titanium in air particulates. Air samples were collected on glass-fiber filters and acid digested prior to analysis. Using EDTA (ethylenediamine tetraacetic acid)–sodium acetate electrolyte at pH 2.0, it was possible to determine all five metals in a single polarographic scan.

Stripping voltammetry has been used for the determination of trace metals in particulate matter. DPASV was used to determine Cd, Pb, Cu and Zn, while the detection of Se required differential pulse cathodic stripping voltammetry (DPCSV). An HMDE was used with both stripping methods. The only sample pretreatment required was filtration through a filter to remove the coarse particulate matter and adjustment of the filtrate to
pH 2.0 with HCl. Trace metals bound to the airborne dust particles were determined by subjecting the collected particles, together with the filter media, to low-temperature ashing. In this way, the metal ions contained in the organic layer on the surface of the dust particles were digested completely and were accessible to subsequent DPASV measurement.

Adsorptive CSV has been applied to determinations of Cu, Cd, Ni, and Co in atmospheric samples. For determination of Pb and Cd, samples were collected on glass-fiber filters and were analyzed by DPASV.

For the trace metal determination of Pb and Cd, stripping voltammetry and measurements based on ion selective electrodes were used. A review of advances in EC sensor technology which have attempted to improve the performance of these devices. Three main areas of development have been addressed: advances in sensor design and measurement techniques, novel approaches to increasing electrode selectivity and the use of microminiaturization and microelectronics fabrication techniques. An improved voltammetric procedure has been developed for determination of Zn, Cd, Pb, and Cu.

3.4 Sources

The existence of metals in the environment is a result of both natural and artificial processes. Lithogenic origins, e.g. ore deposits and volcanoes, were the predominant sources of metal before the Industrial Revolution. However, the present-day levels of heavy metals in the environment are almost exclusively from anthropogenic sources. These metals are released into the environment either directly by wastewater discharges and run-off, or indirectly via the atmosphere adsorbed onto precipitates and dust. Owing to the ubiquity of heavy metals in the environment, they can become incorporated in food chains and drinking water, eventually being taken up by humans.

Among the most hazardous heavy metals are Cd, Pb and Hg. These three metals are toxic at all concentrations and have no biological requirement. A second group of metals, containing As, Bi, In, Sb and Tl, have no biochemical requirement by man and are only tolerated at trace levels in biochemical systems. Finally, there is a third group of metals which are known to be biochemically essential. Among these essential elements are Cu, Zn, Co, Ni, V, Se, Cr and Fe. Even this last group of metals, though essential below their respective threshold levels, become progressively toxic above certain levels. Some of these metals, e.g. Ni, Cr, Cu and Se, are known to display carcinogenic effects due to their interaction with nucleic acids.

In general, the toxicity of metals stems from the fact that they are biologically nondegradable and have a tendency to accumulate in vital organs, e.g. brain, liver or bones of humans, and by their accumulation become progressively more toxic. However, the degree of toxicity exerted on a biological system depends on the chemical form or oxidation state of the particular heavy metal. For example, studies have revealed that ionic copper is far more toxic towards aquatic organisms than copper bound by organic ligands, and that the more stable the copper complex, the lower is its toxicity. It is also known that As(III) is much more toxic than As(V).

Perhaps the most insidious forms of heavy metals are their alkylated derivatives. Many of such compounds, e.g. alkylleads and alkyltins, have been found in environmental samples. Apart from anthropogenic sources, some of these compounds are produced naturally by chemical or biological processes. Consequently, many heavy metals released into the environment can become even more toxic once transformed to their alkylated forms. In particular, the alkyl compounds of mercury and lead are especially toxic because they are lipid-soluble. Generally, the toxicity of alkylated species tends to increase with the degree of alkyl substitution and carbon chain length of the alkyl group.

3.4.1 Fixed Sources

In the category of fixed or stationary sources of airborne environmental pollutants, a broad range of types and kinds of source encompasses industrial to natural sources such as minerals, soils, waters, some plants and volcanic eruptions. Industrial and fugitive emissions, incinerators, stacks, residues and nuclear plants are among the fixed sources of airborne pollutants. Municipal incinerators are those in which the fuel or feedstock principally originates from domestic waste including paper, wood, kitchen scraps, and so forth. In contrast to the strong interest in organic compounds found in emissions from municipal incinerators, few reports have been found on the subject of metals, especially toxic metals, in the flue gases from such incinerators. The interest in metals in such effluent or flue gases is restricted to mercury, hexavalent chromium, arsenic, gallium, lead and selenium. The trace metals in emissions from coal-fired incinerators can be determined by AAS, NAA, PIXE as well as by electroanalytical methods.

3.4.2 Mobile Sources

Mobile sources, particularly vehicles with internal combustion engines, have been examined since the 1970s for the chemical composition of their exhausts. Various mobile sources were targeted for chemical characterization of airborne pollutants and these included exhausts.
from combustion-based engines with gasoline and with diesel fuels jet craft engines and cigarettes. Cigarettes can also be regarded as a type of mobile airborne pollutant source both outdoors and indoors. Tobacco smoke condensates were analyzed as an indoor pollutant for metals such as As, Cd, and Pb at toxicologically relevant concentrations and for Se.

3.4.3 Ambient Air

Analysis of air in urban and industrial settings for inorganics, principally metals, has been accomplished using several techniques such as PIXE, X-ray fluorescence measurement, NAA and also electroanalytical techniques. Sample collection is waste volume filtering of air with trapping of particles which are later analyzed. A comparatively high level of interest was taken in metal determination in nonurban or natural locations. Examples are analyses of marine aerosols for Ti, Cr, Fe, and Ni determination of transition metals in aerosols at the Brazilian Antarctic Station and at a biomass burning site in the Amazon basin. Other examples include determinations of metal ions in the auroral lower E-region and of atmospheric aluminum in the air at the French Riviera compared with determinations of Pb, Cd, Cu and Zn in Saharan dust. Zn, Cd, Pb and Cu ions in ambient air can be determined by ASV.

3.5 Accidents and Emergencies

Air monitoring during accidents or emergencies has received little attention, presumably due to the unplanned or unscheduled nature of an emergency and the speed at which events can overtake systematic sampling and analysis. The fallout and environmental poisoning from the Chernobyl nuclear facility figured prominently in terms of 235U in soil particles as a source of dust and of 90Sr in filters in the late postaccident period using gamma spectroscopy. Vehicle fires in traffic tunnels, a special type of emergency, were considered in terms of sampling strategies with a mixture of passive and active collectors.

3.6 Atmospheric Chemistry, Transport and Deposition

Wet deposition includes the collection of airborne pollutants in condensed rather than vapor form within rain drops, snow, or liquid aerosols (fog).

Davidson discusses the mechanisms of wet and dry deposition on snow. The determination of heavy metals is complicated by adsorption on the collection funnel walls and by contamination of Cd and Zn from metal surfaces. Programs and analytical methods for rainwater monitoring have been developed.

Ultratrace determinations of heavy metals can be carried out in rainwater and in snow and ice.

4 WATER ANALYSIS

Throughout history, the quality of drinking water has been a factor in determining human welfare. Currently, waterborne toxic chemicals pose the greatest threat to the safety of water supplies in industrialized nations. The quality of groundwater is subject to a number of chemical influences. There are many possible sources of chemical contamination of water. These include wastes from industrial chemical production, metal plating operations, and pesticide runoff from agricultural lands. Some specific pollutants include industrial chemicals such as chlorinated hydrocarbons, heavy metals (including cadmium, lead and mercury), saline water, bacteria and general municipal and industrial wastes. Since World War II there has been a tremendous growth in the manufacture and use of synthetic chemicals. Many of the chemicals used or manufactured by industry have contaminated water supplies. Water pollution should be a concern of every citizen. Understanding the sources, interactions, and effects of water pollutants is essential for controlling pollutants in an environmentally safe and economically acceptable manner.

Some of the heavy metals are significant water pollutants. Cadmium, copper, lead and mercury ions bind to cell membranes, hindering transport processes through the cell wall. Heavy metals may also precipitate phosphate-containing biochemicals or catalyze their decomposition. Some of the metalloids, arsenic, selenium, and antimony, are also known as significant pollutants. Manufacture of inorganic chemicals has the potential to contaminate water with trace elements. Among the industries regulated for potential trace element pollution of water are those producing sodium dichromate, chloralkali, hydrofluoric acid, aluminum fluoride, chrome pigments, copper sulfate, nickel sulfate, sodium bisulfate, sodium bisulfite, sodium hydrosulfate, titanium dioxide, hydrogen cyanide and various plating industries.

4.1 Reviews and Monographs

There are an increasing number of articles appearing in the literature describing the analysis of trace pollutants in environmental waters. Toxicity data for many hazardous compounds were compiled by the European Chemical Industry Ecology and Toxicology Centre selection criteria and the structure of this database and its uses have been described. Soluble filters can be used for preconcentration of trace elements in water. Contamination in the course of analysis of trace metals can
be minimized.\(^{122}\) Other topics discussed are instrumentation and automation used in wastewater treatment,\(^{123}\) pollutant monitoring and determination,\(^{124}\) as well as analytical methods for the determination of trace components.\(^{125}\) Analytical techniques, as applied to water analysis, including in situ voltammetric measurements, were described in a review containing 154 references.\(^{126}\)

### 4.2 Sample Collection

Sample collection is a very important step in determination of traces of metals in water. The first problem is to choose the type of sampling bottle that will be used. When the often preferred high-pressure (low-density) polyethylene bottles are used,\(^{127}\) they should be degreased and leached by an acid to remove trace metals present.\(^{127}\) Alternatively, Teflon\(^{TM}\) bottles may be used as this is the only material that does not release zinc into a water sample.\(^{128}\) Surface water samples taken in the open ocean cannot be taken directly from a large ship because the ship is continually releasing copper, lead and zinc from its antifouling paints and cathodic protection devices.\(^{129}\)

In such situations, the only safe way to sample is to use a small rubber dinghy which is rowed to the sampling site. Sampling is undertaken at the bow of the boat whilst slowly rowing into the wind to prevent contamination of the sampled water by the boat.\(^{130}\) Collection of surface samples from coastal waters, estuaries, rivers and lakes is usually undertaken from small boats using a telescop bar with an attached sample bottle.\(^{127}\)

For the collection of samples at depths greater than 10 m the aforementioned methods are unsuitable. The normal procedure involves clamping a sampler to a hydro wire and lowering the sampler to the required sampling depth. However, this method is prone to sample contamination by rust and grease from the hydro wire.\(^{131}\) This procedure can introduce a large amount of trace metal contamination, especially lead. These contamination problems can be circumvented by using the all-Teflon\(^{TM}\) Patterson CIT sampler.\(^{132}\) This is one of the few sampling devices that can collect deep seawater samples without metal contamination.

### 4.2.1 Storage of Water Samples

Storage methods employed depend on the nature of the measurements which are to be undertaken. For speciation studies, water samples should not be acidified as this would change the nature of the speciation.\(^{133}\) Likewise, freezing of water samples is not possible. As a water sample freezes, metal ions are concentrated in the unfrozen liquid in the center of the container, where they may undergo chemical and physical alteration.\(^{129}\) Thus, samples for speciation studies should be filtered through a 0.45-µm membrane filter to remove any suspended material. The filtrate, containing the dissolved heavy metal fraction, should subsequently be stored at 4°C, as this appears to be the safest method for both freshwater and seawater samples.\(^{134,135}\) Storage of samples at higher temperatures may result in speciation changes. This has been observed for cobalt and manganese when water samples were stored at room temperature.\(^{136}\) Changes induced by a pH drop due to bacterial respiration, in which oxygen was consumed and carbon dioxide was released, resulted in precipitation of cobalt and manganese carbonates.

If the total concentration of dissolved heavy metals is to be determined in a water sample, then the filtered sample is usually adjusted to pH 2.0 by adding a small amount (1 mL L\(^{-1}\)) of concentrated hydrochloric acid or perchloric acid.\(^{6}\) Acidification of the sample helps prevent loss of metal by adsorption on the walls of the storage container. However, in some instances, acidification may cause leaching of metals, especially lead and zinc from the container walls.\(^{127}\) The best method of sample storage is freezing to −20°C or at liquid nitrogen temperature.\(^{137}\) This eliminates leaching of trace metals from the container and also losses by adsorption.

When filtered samples are stored at room temperature for less than a week, acidification is unnecessary.\(^{138}\) In the case of long-term storage, filtered samples, whether acidified to pH 2.0 or unacidified, have to be deep frozen.\(^{138}\)

### 4.3 Techniques

Polarographic and voltammetric methods are mostly used in water analysis. Among the polarographic methods the most sensitive direct method of analysis is DPP. It has been used to determine the total chromium content of a river water sample.\(^{139}\) Before DP polarographic analysis, all chromium present in the water sample was converted to Cr(VI) by oxidation with H\(_2\)O\(_2\) followed by determination in 1 M NaOH. The result was to be in good agreement with that obtained by flame AAS.

Direct determination of As(III) and Pb(II) in the run-off water from waste disposal grounds has also been accomplished by DPP.\(^{140}\) The sample pretreatment simply consisted of addition of a supporting electrolyte (2 M NaCl and 2 M H\(_2\)SO\(_4\)) followed by deaeration and recording the DP polarogram at a DME. The complete analysis took 20 min to perform. A high sulfuric acid content was required to ensure sufficient separation of the responses of Pb(II) and As(III). If As(V) is present, it must first be reduced to As(III) using hydrazine, before it can be determined. With this method, determination limits of 40 µg L\(^{-1}\) or less are attainable. Generally,
direct determinations are only possible when the metal concentrations are sufficiently high. For example, the detection limit for cadmium in water matrices is 10 µg L⁻¹ when DPP is used.

When surface active organic traces are present, the detection limit is restricted to higher concentrations. For the determination of ultratrace levels of metals, stripping voltammetry is required. The voltammetric mode most frequently used for the determination of metals at such ultratrace levels is DPASV. This method has been successfully applied for the determination of trace metals in rainwater, seawater, freshwater, saline water and snow samples. Ni and Co can be simultaneously determined in rainwater samples. ASV, CSV and adsorptive stripping voltammetric methods are also among the most frequently used methods.

Many new procedures for trace analyses include determinations of iron, aluminum, zinc, platinum, molybdenum, copper, titanium, nickel and cobalt, and cadmium, lead and copper, in seawater, rainwater and river water by using some chelating agents.

A development in environmental analysis has been the construction of on-line sensors for trace metals based on stripping analysis. An automatic voltammetric analyzer for the determination of four trace metals (Cd, Pb, Cu and Zn) in water has been developed. This analyzer was employed for the intermittent on-line analysis of tapwater supplied by water works, although it can also be applied to the analysis of wastewaters. With this device, samples are automatically taken from the mains water supply, acidified and analyzed by DPASV at an HMDE. Each sample solution is analyzed twice followed by two standard additions for calibration purposes. The detection limit is 0.1 µg L⁻¹.

Another form of automated system is a flow injection analysis (FIA) using ASV for detection. In this type of system, small volumes of sample solution are injected into a carrier stream, which transports them towards the detector. Deposition occurs while the sample is flowing through the detector and the stripping step is effected after the sample volume has passed the detector. The most commonly used electrodes are the HMDE and MFE. Solid gold electrodes are used for monitoring metals with oxidation potentials more positive than that of mercury. The stripping mode utilized depends on the analyte concentration. The linear mode is used to monitor in the 5–50 µg L⁻¹ concentration range. In this concentration range, short deposition periods (1–3 min) are employed so that the analysis takes 2–4 min, which means that carrying out 15–30 measurements per hour is possible. At lower concentrations the DP mode is used, but this considerably lengthens the time of each analysis, given the slow scan rate (2–5 mV s⁻¹) in the stripping stage. An automated ASV flow system, based on a mercury-coated graphite tubular electrode, has been applied to the continuous monitoring of copper and zinc in marine environments.

Another type of a flow-through detection system for the determination of trace metals involves combining high-performance liquid chromatography (HPLC) with EC detection. An example of such an approach is the selective determination of copper in tapwater using reversed-phase HPLC. It involves complexation of copper with dithiocarbamate (DTC) ligands. The preferred method for formation of the Cu(DTC)₂ complex was inclusion of a DTC salt in the mobile phase and injection of the aqueous sample onto the column to form the complex in situ. Determination of the copper complex, using the oxidative process, was undertaken at a gold electrode. The DC response of the electrode was monitored at +0.6 V. The results by this HPLC/EC detection method were compared with those obtained by AAS, and excellent agreement has been found for results obtained by these two methods. The use of HPLC with EC detection has also been extended to multielement determinations. By forming diethyldithiocarbamate complexes of Cu, Ni, Cr and Co it was possible to determine simultaneously all four metals. When pyrrolidine DTC was used as the complexing ligand, Cd, Cu, Co, Pb, Hg and Ni were determined.

Other electroanalytical methods used in trace metal analysis include anodic stripping coulometry and (chrono)potentiometric stripping analysis (PSA), which is a relatively new analytical method, but resembles voltammetric stripping analysis by involving two discrete steps. In the first step, the analytes are deposited at or dissolved in a suitable electrode by application of an appropriate potential. In the second step, the preconcentrated analyte is stripped at a constant or zero current and change in the potential of the working electrode is recorded as a function of time. Both oxidative and reductive PSA methods have now been developed.

The APASA on-line analyzer by Tacussel is designed for control in water processing plants. It automatically performs on-line polarographic determination of trace amounts of Ni, Zn, Cd, Pb, Cu and Cr in primary waters of rivers, estuaries, seawater and so on. A built-in ultraviolet mineralization stage allows the system to treat waters loaded with organic material directly. The water is filtered before being pumped into the EC system for final sample preparation and analysis. Metrohm has recently marketed an automatic VA Trace Analyser that incorporates an autosampler.

4.4 Sources
The role of surface waters, rivers, and lakes as pollutant transporters, as well as analyses of groundwater, drinking
water, seawater, municipal wastewater and industrial wastewater will be discussed in this section.

4.4.1 Surface Water, Rivers and Lakes

Interest in surface waters has increased, and this trend reflects an increased awareness of the importance of lakes and rivers in the transport of pollutants. Inorganic analytes were studied most often. Examples are the use of DPP in determination of the total chromium content of river water\(^{139}\) or that of DPASV for a simultaneous determination of Tl(I) and (CH\(_3\))\(_2\)Tl(I) ionic species in buffered lake water samples with estimated detection limits of 3.2 ppb and 3.4 ppb, respectively.\(^{163}\) Since the consequences of mixing organothallium compounds with mercury salts were unknown, the plating of a thin mercury film on a GCE was performed separately from the sample deposition step, rather than using in situ film deposition and compound accumulation. The other heavy metal ions such as Pb(II), Zn(II) and Cd(II) interfere in the determination of the thallium species, so that an addition of EDTA is necessary, which results in a slight shift of the peak potentials to more negative values and in a decrease in the peak current due to Tl(I) ion. One of the simplest procedures based on an ASV measurement has been developed for the speciation of copper in river water.\(^{164}\) In this scheme samples of water were adjusted to pH 8.0 and the copper content measured by DPASV. Following this step the sample was acidified to pH 2.0 and the copper concentration was again determined. There was a tenfold increase in the measurable copper concentration on decreasing the pH of the water sample. The smaller stripping current at high pH was attributed to the nonlabile nature of the copper species present. The nickel and cobalt level of the surface water of the Mediterranean Sea was determined by adsorptive cathodic stripping square-wave voltammetry.\(^{165}\) The concentration of the dissolved cobalt ions in the surface water was 0.168 nM but it decreased to 0.045 nM at a depth of about 300 m.

4.4.2 Groundwater

Two reviews\(^{166,167}\) and a monograph covering the problem of groundwater contamination\(^{168}\) have been published. Some other reports have described the monitoring program at Savannah River,\(^{169}\) the quality control program at Hanford,\(^{170}\) and an overview of statistical methods for groundwater monitoring.\(^{171}\) Monitoring data from 500 waste disposal sites showed that volatile organic compounds are the most abundant class of organic contaminants in groundwater. Adsorptive catalytic stripping voltammetry was used for the determination of total chromium in groundwater with a detection limit of 1 ppt.\(^{172}\) DPP and differential pulse catalytic adsorptive stripping voltammetry (DPCASV) techniques were used for the speciation analysis of organic and inorganic Se compounds in natural waters. The detection limit was 10 µg L\(^{-1}\) in the DPP analysis and 0.04 µg L\(^{-1}\) in the DPCASV analysis.\(^{173}\)

4.4.3 Drinking Water

Contamination of drinking water and the natural environment by toxic metals is a serious problem. In the USA alone there are over 30,000 abandoned chemical dump sites, many of which are leaking various pollutants into sources of local waters. This provides a strong incentive for the development of continuous metal analyzers. Monitoring of drinking water is demanding since the permissible metal levels are very low, generally at parts per billion levels (US Environmental Protection Agency recommended standards are Pb 0.005 ppm and Cu 0.02 ppm). Using a portable (chrono) potentiometric stripping analyzer, Cu(II) at 0.1–5 ppm and Pb(II) at 1–50 ppb could be detected in a 0.4-mL drinking water sample.\(^{174}\)

4.4.4 Seawater

Great interest has been shown in the analysis of seawater, as reflected by the development of new methods for the determination of inorganic species. Speciation studies of Cu and Ni use competitive ligand equilibration CSV, DPASV and graphite furnace AAS.\(^{175}\) Mercury is determined by ASV with a GCE spin coated with a hexacosane derivative.\(^{176}\) Arsenic is determined by CSV.\(^{177}\)

A particularly important area of study is the quantification of dissolved metal species in both freshwater and seawater samples. Electroanalytical determination of the dissolved metal content in these samples requires a limited sample pretreatment, which minimizes error sources arising from contamination. The usual procedure involves sample filtration through a 0.45-µm filter to remove particulate matter present and acidification of the filtrate to pH 2.0 with concentrated HCl. Samples are usually left to stand for several hours to allow the completion of decomposition of most complexes present. The metal ions Cu, Cd and Pb are then simultaneously determined by DPASV at an MFE, with the possibility of determining these three metals to levels as low as 1 ng L\(^{-1}\).\(^{178}\) Because of the lower hydrogen overvoltage of the MFE, less negative plating potentials of −1.0 V are applied in media at pH 2.0. Hence, zinc which is reduced at more negative potentials has to be determined separately at pH 4.5.\(^{6}\)

ASV is especially suited for the analysis of seawater and other saline waters because the high-salt matrix...
was also proposed microgram per liter level. A routine speciation method was also proposed in a pollution survey of coastal seawater. A combination of DPASV at an HMDE and linear ASV was used with collection at a rotating ring disc electrode (RRDE) for identification of soluble Zn, Cd, Pb, Cu, Bi and Sb trace metal species. A limit of detection between 0.005 and 0.25 mg L$^{-1}$ was obtained for antimony determination. A simple method that allows Sb(III) and Sb(V) to be determined selectively is based on CSV after accumulation as amalgam from hydrochloric acid solutions. The disadvantage of this simple method is the interference of bismuth and copper. It is possible to determine dissolved antimony as well as Sb(III) in freshwater and seawater by CSV in the presence of catechol with a detection limit for Sb of 0.16 mmol L$^{-1}$. Alternatively it is possible to differentiate antimony oxidation states using AD$$v$$ with chloranilic acid as a complexing agent. Spiked seawater samples were analyzed and detection limits of 210 ng L$^{-1}$ for Sb(III) with 5 min preconcentration and 560 ng L$^{-1}$ for Sb(V) with 10 min preconcentration were reported. Another study revealed that antimony could be accumulated in the presence of triphenylmethane dyes in order to develop more sensitive and selective methods for antimony speciation. Automated constant-current stripping analysis for Sb(III) and Sb(V) with gold-fiber working electrodes enabled analyses of river and seawater reference samples at microgram per liter levels. DPASV using an MFE has been employed to determine the levels of dissolved Cd, Pb and Cu in coastal and inland waters. This study revealed that Cd and Pb levels were usually elevated along main shipping routes, while in the immediate vicinity of these routes the levels dropped abruptly to the values of the local coastal waters. It was also found that areas where the water is rich in suspended particulate matter tended to have low dissolved metal concentrations, typically 5 ng L$^{-1}$ Cd, 18 ng L$^{-1}$ Pb and 130 ng L$^{-1}$ Cu. This is related to the high metal uptake by plankton organisms and/or metal trapping due to chemisorption at suspended inorganic and dead organic matter surfaces.

A recent survey used DPASV at an MFE to determine total and dissolved concentrations of Cd distributed in coastal and open ocean waters. This survey found that coastal waters contained higher cadmium concentrations than open ocean waters. Generally, cadmium was preferentially present in the dissolved state, although in heavily polluted waters with large amounts of suspended particulate matter, the total levels were higher than the dissolved contents. Because Cd was present preferentially in the dissolved state, it was suggested that it can be used as a suitable tracer when studying the movement of pollution plumes in coastal waters.

Another toxic metal frequently found in the environment is mercury. A method has been developed for the determination of mercury in water samples, after acidification of the sample to pH 1.0, by DPASV at an activated gold electrode. The detection limit of the method was 50 ng L$^{-1}$. This method was found to be suitable for the simultaneous determination of copper and mercury. Furthermore, for high levels of copper, the gold electrode is more suitable than the mercury electrode, because problems associated with the limited solubility of copper as an amalgam in mercury are eliminated. For the determination of copper in seawater, medium exchange after the plating stage was necessary. This was required because the response corresponding to chloride oxidation interferes, and the chloride formed would damage the surface of the gold electrode. For the determination of ultratrace levels, below 30 to 50 ng L$^{-1}$ in seawater, a method based on DPASV in the subtractive mode at a twin gold electrode was recommended. The separation of the two halves of the gold disc by an insulating epoxy resin allows application of different potentials to both halves. Operation of the subtractive mode ensures a low background current. There was good correlation between results obtained by this method and those by cold vapor AAS. However, as the voltammetric response is complicated, it was suggested that for routine ultratrace determinations of Hg the application of cold vapor AAS was more convenient.

The voltammetric determination of mercury in seawater has been improved by using an epoxy resin-cast gold disc electrode, which allows extremely low concentrations of the toxic metal to be detected (2 ng L$^{-1}$). Seawater samples collected off the Swedish coast in both the Baltic and North Seas were analyzed by DPASV with a gold disc electrode, yielding mercury concentrations of 8.8 and 7.0 ng L$^{-1}$, respectively, with a precision of about ±20%.

Adsorptive CSV has been applied for the determination of many trace elements in seawater. A review including 51 references by Van Den Berg discussed the applications of this technique to analysis of seawater. The preconcentration step in this method can consist of precipitation of an insoluble salt, or adsorption of a surface-active complex, prior to the reduction of the deposited material. The former method gives an irreversible reduction current, and is therefore not very sensitive to low concentrations of trace elements. The latter procedure results in the formation of a monolayer of complexed species at the surface of the mercury electrode, which is reduced reversibly and completely, yielding a high sensitivity. A variety of ligands have been used to
form adsorptive complexes useful for the determination of trace elements in seawater. Among them catechol was found suitable for the determination of Cu, Fe, Sb, Sn, V at pH levels of 6 to 8. DMG was used for the determination of Co, Ni and Pd at pH 8–10. nioxime for that of Co at pH 7.5, quinolin-8-ol for Cd, Cu, Mo, Pb and U at pH 7–9. diethylenetriaminepentaacetic acid (DTPA) for Cr, mandelic acid (MA) for Ti at pH of 3.0 and tropolone for Mo and Sn at pH 2.0 in seawater samples. In these procedures the reduction of the metal ion from the adsorbed complex took place in the stripping phase. Platinum in seawater was determined by the catalytic current of hydrogen evolution in 0.5 M sulfuric acid medium. The total tin in estuarine waters was determined by adsorptive CSV using tropolone as the complexing ligand. A deposition potential of −0.8 V and a reoxidation potential of −0.4 V were used. Starting at the latter, the current–voltage was next recorded toward more negative potentials. Samples had to be ultraviolet photolyzed prior to analysis in order to remove interfering surface-active organic compounds. The limit of detection was 5 pM tin using a 10-min stirred deposition prior to the scan.

The total tin content in the shipyard water was determined by DPP. A 100-mL sample solution was evaporated until 5–7 mL remained, then Sn(II) was oxidized in acidic solution with H2O2 to Sn(IV). In an EDTA solution at pH 5 the interference of lead could be eliminated and tin level of the water was found to be 1.2 × 10−6 M. For the simultaneous determination of Co and Ni in seawater, adsorptive cathodic stripping square-wave voltammetry has been applied. Here the complexes of cobalt and nickel with DMG are analyzed by a voltammetric method based on adsorptive collection at an HMDE. This method had greater sensitivity than the DPCSV method and a faster scan rate. At pH 8.0, with an adsorption potential of −0.7 V and adsorption time of 60–180 s, depending on the concentration of cobalt and nickel in the sample, and a scan rate of 140 mV s−1, detection limits for cobalt and nickel were obtained at approximately 8 pM and 0.05 pM, respectively.

The accuracy of the method for the determination of Bi(III) in seawater at its natural pH of 8.1 is similar to those previously reported for strongly acidified samples. This method employs the square-wave mode for the anodic potential scanning at a bare glassy carbon rotating-disc electrode instead of at a mercury-plated one. In seawater, the GCE is highly selective for bismuth in the presence of the other commonly found metal ions; only Cu(II) reacts, but bismuth can be determined even in the presence of a 100-fold concentration of Cu(II) by selecting an appropriate accumulation potential. This method is sensitive to bismuth ions (including hydrated Bi(III), oxy- and hydroxy-species and various labile complexes) and not to its total concentration. The bismuth content in a sample collected near the coast of Heligoland was found to be 12 ± 2 ng L−1. The newly developed PSA method has been used for the determination of Pb, Cd and Zn in seawater using an MFE.

### 4.4.5 Municipal Wastewater

Inorganic species of concern included Pb and Cd and free available chlorine and total residual chlorine. Several commercial instruments designed for field analysis of toxic metals have been introduced. A portable, semi-on-line voltammetric analyzer developed by Chemtronics uses a glassy carbon working electrode, operates on 0.1–5-mL batch samples and provides automatic deaeration and system calibration. Targeted at industrial effluent and domestic water supply analysis, measurable metals include Sb, As, Bi, Cd, Cu, Au, Pb, Hg, Ti, and Zn over the concentration range down to 10 ppb.

### 4.4.6 Industrial Wastewaters

Studies on the analyses or composition of wastewaters from industry or the other facilities such as governmental laboratories can be divided conveniently into categories by product or activity. The pulp and paper industries, miscellaneous manufacturing industries, chemical industries, and plating or tannery and dye manufacture industries are the main sources of inorganic species causing water pollution. As the contamination of the natural environment by toxic metals is important, all water runoffs have to be monitored for many of the major pollutants. This is providing a strong incentive for the development of continuous metal analyzers. The other major incentive is the need to monitor effluents from existing waste generators such as electroplating plants, manufacturers of electronics products and some mining operations. In these applications two types of analytical measurement are generally required. In the first, monitoring of the performance of waste treatment equipment is carried out to detect a malfunction, for example saturation of an ion-exchange column. The second type of measurement is an end-of-pipe analysis to ensure that the plant discharge meets compliance. In the former case, fairly simple metal monitors which can provide an alarm response in the range 5–20 ppm are adequate whereas the requirements for discharge monitoring are much more rigorous. These may be required to indicate compliance with the local discharge standards which in California, for example, are 0.1 ppm for Pb and 0.5 ppm for Cu. Trace metals in wastewater streams are also routinely determined for wastewater management. The concentrations of the metals can vary considerably as a function of time because of the level and type of activity at the generating source. Thus online, near real-time measurement capabilities are highly
desired. An example is an on-line voltammetric analyzer for trace metals in wastewater. By this device, Cr, Ni, Zn, Cd, Pb and Cu were determined automatically with detection limits close to 50 µg L⁻¹ to characterize a wastewater stream.

For automated trace metal analysis on-line ASV is now the technique of choice. In the last few years there have been some major advances in cell design, instrumentation and control systems. An improved version of the wall-jet cell using microprocessor control has been used in continuous flow ASV, while a similar approach using a thin-layer cell and flow injection has also been described. Eutech Cybernetics has developed a hand-held metal monitor, also based on the ASV principle. A novel feature of this system is the use of disposable electrode strips on which the electrodes have been screen printed. Designed as a dedicated metal monitor for copper or lead, each unit has been high and low operating ranges: 0.01−0.7 ppm and 0.5−3.0 ppm. The main application of the Electrascan is also for monitoring of drinking water and of industrial effluents. The use of disposable electrodes, as was discussed earlier, has some significant advantages including elimination of the need for electrode preconditioning which is a tedious feature of most stripping voltammetric methods. It also avoids problems of cross-contamination of samples which may occur in continuous flow systems. A two-point calibration is first carried out using one of the two electrodes in the Electrascan sample chamber, using calibrating standards. Next, one drop of the activating solution is added to a 1.0-mL sample, then a 100-µL aliquot is introduced into the cell chamber. The analysis is completed and the result displayed in approximately 100 s. Improvement in the design and fabrication of the DME by Novotny and Heyrovski has provided a much more robust, versatile sensor with wide ranging applications in environmental monitoring. Potentiometry was used to determine Hg(II) in chloralkali effluents.

5 SOIL AND SEDIMENT ANALYSIS

Metals are released into the environment either directly by wastewater discharges and runoff, or indirectly via the atmosphere adsorbed to precipitates and dust. Because of the large quantities of heavy metals in the environment, they can become incorporated in food chains and drinking water, eventually being taken up by humans. The lead content of roadside soil has been found to vary between 100 and 3000 ppm, depending on the location and the volume of traffic. In contrast, the average lead content of the earth’s crust is about 16 ppm. Marten and Hammond investigated three types of soil samples and found that samples near a battery smelter, near a road, and from a greenhouse contained 680, 59, and 12 ppm of lead, respectively. Most of the lead in soil exists in sparingly soluble forms. When 2784 ppm of lead nitrate were added to soil, it was found that after three days the soluble lead content was only 17 ppm. It is to be expected that all ions in nature will accumulate as their less soluble compounds, such as oxides, carbonates, silicates and sulfates, the relative proportions of each depending on the nature of the soil and on the solubility. Meat, seafood, milk, eggs and many other foods are sources of many toxic elements. The amount of these elements is influenced by the element content of the soil. The minerals move from the soil to the plants that grow on it, then to the animals that eat plants. The concentration of selenium in human milk samples obtained from vegetarian women was significantly greater (22 ng mL⁻¹) than from nonvegetarian women (16 ng mL⁻¹). The milk samples obtained from a farm which was near to a road supporting heavy traffic contained 60 µg L⁻¹ lead, whereas 22 µg L⁻¹ of lead was normally expected.

5.1 Reviews

Although considerable work on the determination of metals in soils and sediments has been reported, most studies represent small improvements in the application of existing methodology rather than novel analytical approaches. In a natural aquatic environment heavy metals will be deposited in the surface layers of sediments. Although sediments contain the greatest concentration of metals, only a few studies on the speciation of heavy metals in sediments have been undertaken. Chemo-metric techniques can be used to investigate to what extent soil sampling presents a representative picture of soil as a whole. Three methods of fluvial sediment sampling were studied to determine how valid and representative is the geochemical information obtained from each technique. Bottom sediments and trap sediments showed similar results for metals. Methods for the determination of heavy metals in soils and sediments were reported in many studies. The chemical speciation and environmental mobility of heavy metals were reviewed by Sager. An interlaboratory study where the extraction techniques were specified but the measurement method was optional showed a strongly differing degree of comparability for the various elements, extraction techniques, and measurement techniques used by the different laboratories. In other studies, the use of an ultrasonic slurry sampler and the recovery efficiencies of heavy metals during acid digestion by different acid mixtures and by block heater and microwave heating were reported. Developments in the analysis of estuarine and coastal sediments for heavy metals have been
5.2 Sampling

Problems associated with techniques and strategies of soil sampling have been reviewed. Various sampling schemes for soils have been described. Different sampling designs are needed, depending upon whether the soil contamination is expected to be “spread” over the whole area or exists in localized “hot spots.” A decision-support system for the sampling of aquatic sediments in lakes was described by Wehrens et al. and was applied to a real environmental problem. Lame and Defize showed that the fundamental sampling error for soils affects the analytical variance only when sample sizes are less than 10 g. For larger samples, the variance is determined by the segregation error. A sampling board method for estimation of the segregation error was described. A two-way compositing strategy can be used to attribute detected contamination in composited samples directly to constituent samples without further analyses.

Evaluation of various soil and sediment samplers has been reported. The sediment shovel proved highly practical, but was limited because small particles tend to be lost when the shovel is lifted. A cryogenic sediment sampler was less convenient to use, but allowed the collection of nearly undisturbed samples. Another device has been suggested for the automatic subsampling of soil, sediment and plant material for proficiency testing. In another study, freeze-sampling collects representative sediment samples, whereas grab-sampling introduces a bias in the textural composition of the 120-mesh fraction, caused by washout and elutriation of the finer fractions.

5.2.1 Sample Preparation

The risks of sample contamination using inappropriate materials, containers and tools, as well as possible analyte loss during sample handling, have been discussed. The influence of grinding procedures was discussed in another study, which found that the availability of some analytes was significantly influenced by the degree of grinding in some soils.

Significant interest still exists in microwave extraction methods. In one investigation, the microwave extraction of cadmium in a soil reference material gave results comparable to those found after using conventional extraction procedures. In another study, microwave versus conventional dissolution was compared for soils, sludges, sediments, and oils. By microwave digestion of dust samples with a nitric acid/hydrofluoric acid mixture, over 90% of Pb and Cd were recovered within 30 min. Microwave digestion procedures for the analysis of metal-contaminated soils were also reviewed.

Other extraction procedures for metals in soils and sediments were studied. For the determination of lead in roadside soil, HCl, HNO₃, HClO₄, aqua regia and EDTA were used for the digestion. Among them the digestion with a mixture of aqua regia and EDTA yielded the highest level of lead content. However, 90% extraction was possible when EDTA was used as the extraction medium. The EDTA extraction procedure was evaluated in a collaborative study between six laboratories. All laboratories produced some extreme outlying results, but most results were in good agreement once the outliers were removed. Acceptable accuracy and precision were obtained for metals in soil using an ultrasonic bath digestion procedure. An interlaboratory comparison study was reported involving 160 accredited hazardous materials laboratories. In this study, each laboratory performed a mineral acid digestion on five soils spiked with As, Cd, Mo, Se, and Tl.

5.3 Techniques Used for Soil and Sediment Analysis

Square-wave CSV was used for the determination of selenium in soils and sediments. Speciation of As(III) and As(V) in soils was accomplished under different pH conditions by CSV. Other developments in the determination of heavy metals in soil and sediments were reported. The lead content of roadside soil in Ankara was determined using ASV. The deposition potential was −0.800 V in the presence of EDTA and HClO₄ at pH 2.0 and the deposition time was 5 min. After a rest period of 45 s, a potential sweep of 60 mV s⁻¹ was applied in a positive direction and the current was recorded. Under these conditions, 10⁻⁷ M lead could be determined with better than 95% accuracy. As expected the lead content of the soil increased with increasing traffic volume, changing from 193 to 710 ppm. A convenient and accurate analytical procedure has been developed for the simultaneous determination of Cd, Cu, Pb, and Zn in soils. This method is based on DPASV measurement, at an HMDE, of the analytes resulting from the digested soil. Some samples were analyzed by DPASV and AAS to ascertain the applicability of the developed procedure. Good agreement was found between the results obtained with both methods. Selenium has been analyzed in soils and plants by DPCSV at the HMDE. Oxygen-flask digestion of the sample was followed by treatment with HCl to reduce Se(VI) to Se(IV). The voltammogram was then recorded and Se concentration was determined by means of its second
stripping peak. Results obtained by DPCSV showed reasonable agreement with those of fluorimetric analysis for Se content above 0.1 µg g⁻¹, and the detection limit of 5 ng g⁻¹ was similar for both methods. A simple and sensitive adsorptive catalytic stripping (voltammetric and (chrono)potentiometric) procedure for determining trace amounts of chromium in soil samples was developed by Wang et al. [252]. A preconcentration time of 1 min using a preconcentration potential of −0.82 V (versus Ag/AgCl) resulted in a detection limit of 1 ng L⁻¹. The identical stripping response for Cr(III) and Cr(VI) solutions makes the method applicable to the measurement of the total Cr. Groundwater and soil samples from contaminated nuclear energy sites were also analyzed.

Ion chromatography (IC) is a subset of liquid chromatography applied to the determination of ionic solutes, such as inorganic anions, cations, transition metals, and low-molecular-weight organic acids and bases. Although these solutes can be analyzed using a number of separation and detection modes, ion-exchange is the primary separation mode and suppressed conductivity is the primary method of detection in IC. Method detection limits (MDLs) for inorganic anions and cations are typically in the low parts per billion range and recoveries obtained for ions in spiked water samples are generally in the order of 80–110%. The linear calibration range extends from low parts per billion to mid parts per million concentrations for most applications. IC is well established as a regulatory method for the analysis of inorganic anions in environmental samples as there are few alternative methods which can determine multiple anions in a single analysis. However, there are relatively few regulatory methods for cation analysis which use IC. Methods for cation analysis tend to be based upon spectroscopic techniques, although IC offers the advantage of providing information on metal speciation. The main interferences in IC are generally other ions which elute within the timeframe of the ion(s) of interest, and the determination of trace ions in the presence of high levels of other ionic species remains the most difficult of analyses with this technique.

1 INTRODUCTION

1.1 Historical Perspective

The origins of modern IC were laid down by Hamish Small et al. at Dow Chemical in 1975, when they first described a novel ion-exchange chromatographic method for the separation and conductimetric detection of ionic species. They employed a low-capacity, ion-exchange stationary phase for the separation of analyte ions, in conjunction with a second ion-exchange column and conductivity detector, which allowed for continuous monitoring of the eluted ions. The second column was called a ‘stripper’ column (later termed a ‘suppressor’) and served to reduce the background conductance of the eluent and enhance the detectability of the eluted ions. In the case of anion analysis, this was achieved by exchanging hydronium ions from the cation-exchange suppressor for cocations (e.g. sodium) in the eluent, prior to the measurement of conductance. This results in conversion of the eluent anion to its less-conductive weak-acid form, while enhancing the conductance of the analyte ion pair as a result of replacing the less-conductive cocation with the more conductive hydronium ion. The reverse situation can be described for cation analysis, where the suppressor is an anion-exchange column and the eluent is converted to its less-conductive weak-base form. The term ‘IC’ was subsequently introduced when this technology was licensed to the Dionex Corporation for commercial development.

The introduction of IC provided a foundation for renewed interest in the determination of ionic solutes and prompted much investigation into the use of alternative separation and detection approaches for the liquid chromatographic analysis of inorganic compounds. In 1979, Fritz et al. showed that a suppressor was not essential to sensitive conductivity detection, provided that appropriate low-capacity stationary phases and low-conductance eluents were used. In addition, the separation of inorganic ions using traditional C18 reversed-phase columns was also being explored at about the same time. Since that time, a considerable variety of separation and detection methods have been
employed for the determination of ionic species, as discussed in the article Ion Chromatography. This, in turn, has significantly expanded the range of solutes and applications to which IC is now applied.

1.2 Definition and Scope

This diversity has led to the point where IC is typically defined by the range of solutes to which it is applied, rather than any specific combination of separation and detection modes. IC can therefore be considered to encompass liquid chromatographic techniques which can be used for the determination of the following ionic solutes: inorganic anions; inorganic cations including alkali metal, alkaline earth, transition metal, and rare earth ions; low-molecular-weight (water soluble) carboxylic acids plus organic phosphonic and sulfonic acids, including detergents; carbohydrates; low-molecular-weight organic bases; and ionic metal complexes. Ion-exchange remains the primary separation mode used in IC today, although other approaches used for the separation of inorganic species include ion interaction, ion exclusion, and chelation chromatography, in addition to reversed-phase separations of metal complexes. Advances in suppressor technology have improved the sensitivity and ease of use of suppressed conductivity detection, although nonsuppressed conductivity and indirect (or vacancy) detection methods are still employed as alternatives for universal detection. Direct detection methods have proven to be highly selective for ultraviolet (UV)-absorbing or electroactive species, whereas postcolumn derivatization followed by UV/VIS (ultraviolet/visible) absorption or fluorescence is an important detection approach for transition metals, lanthanides, and actinides. Additionally, the use of more advanced detection techniques for IC, such as mass spectrometry (MS) and inductively coupled plasma mass spectrometry (ICP-MS), continue to be explored.

The growth of IC was very rapid because it provided a reliable and accurate method for the simultaneous determination of many common inorganic ions. In the early stages of its development, IC was viewed as a tool for the determination of simple inorganic species, particularly in environmental samples. The vast majority of the early applications of IC were for the analysis of inorganic anions and cations in environmental samples, such as air-filter extracts, soil extracts, drinking water, and natural-water samples. As the range of solutes that could be determined by IC continued to expand, so did the application areas in which the technique was applied. In addition to environmental applications, IC is now routinely used for the analysis of ionic compounds in diverse areas. These include the chemical and petrochemical industries, semiconductor and high-purity water applications, food and beverage applications, the clinical and pharmaceutical industries, and mining and metallurgical applications.

IC can now be considered a well-established, mature technique for the analysis of ionic species and many organizations, such as ASTM (American Society for Testing and Materials), AOAC (Association of Official Analytical Chemists), and USEPA (United States Environmental Protection Agency), have standard or regulatory methods of analysis based upon IC. Despite the diverse range of solutes and sample types currently analyzed by IC, environmental analysis continues to be the largest application area in terms of new instrument sales and the total number of samples analyzed. In terms of the solutes analyzed in environmental applications of IC, inorganic anions are by far the most important. The primary reason for this is the lack of alternative methods for anion analysis, which is not the case for cations, where many other instrumental techniques are available. Consequently, the simultaneous analysis of the common inorganic anions in drinking water and wastewater remains the most important routine application of IC.

2 ALTERNATIVE ANALYTICAL TECHNIQUES

IC is a well-established regulatory technique for the analysis of inorganic anions in environmental samples. Acceptance of IC for the analysis of anionic solutes was very rapid, primarily due to the lack of alternative methods that could determine multiple anions in a single analysis. A variety of methods have been employed for the analysis of inorganic anions: traditional spectroscopic techniques such as colorimetry; wet chemical methods such as gravimetric analysis, turbidimetry, and titrimetry; and electrochemical techniques such as the use of an ion-selective electrode (ISE) and amperometric titrations. Many of these methods suffer from interferences and limited sensitivity, they can be labor intensive and are often difficult to automate. The use of flow injection analysis (FIA) enables the automation of certain colorimetric and ISE methods of analysis, although still only for one analyte at a time. Multiple analytes can be determined by adding additional channels to an FIA system; however, this adds complexity and cost to the instrument.

During the early development of IC, many comparisons between wet chemistry methods and IC were performed in order to validate the latter technique. For instance, in a 1984 comparison, IC was found to be equivalent to conventional wet chemistry methods for the determination of common anions (such as chloride, nitrate, and sulfate) in
Cr(III) and Cr(VI) and also Fe(II) and Fe(III).

It can distinguish different metal oxidation states, such as polarography and anodic stripping voltammetry. For instance, as IC is a separation-based technique, it is not surprising that IC quickly became accepted by regulatory bodies worldwide for the analysis of anions in drinking water.

However, the situation regarding the analysis of cations in environmental samples is quite different to the case for anions. Many rapid and sensitive spectroscopic methods (such as AAS (atomic absorption spectroscopy), ICP-AES (inductively coupled plasma atomic emission spectroscopy), and ICP-MS) and electrochemical methods (such as polarography and anodic stripping voltammetry) are available for cation analysis. Many of these are multielement techniques and therefore duplicate one of the major attractions of chromatographic methods. Regulatory methods for cation (metal) analysis in environmental samples tend to be based primarily upon AAS and ICP (inductively coupled plasma) instrumentation. However, IC does offer an advantage over spectroscopic techniques for cation analysis in the area of metal speciation. For instance, as IC is a separation-based technique, it can distinguish different metal oxidation states, such as Cr(III) and Cr(VI) and also Fe(II) and Fe(III)\(^{(13,14)}\). In addition, IC has also been used to determine stable metal complexes, such as metalloxyanides and organic arsenic species.\(^{(15)}\) Nevertheless, there are only a limited number of environmental regulatory methods for cations based upon IC methodology.

### 3 SAMPLE HANDLING AND PREPARATION

The primary concerns when collecting environmental samples for analysis using any measurement technique is that the sample collected is representative of the total sample matrix, and that no contamination occurs during the sampling process.\(^{(15)}\) Also, appropriate storage and preservation of the sample is required, in order that the final sample analysis is representative of the analyte concentrations present when the sample was originally taken from the field. Appropriate procedures for the collection of representative samples are discussed in detail in the article Sampling Considerations for Biomonitoring; however, sample handling and preparation techniques specific to IC analysis are discussed below.

#### 3.1 Sample Storage and Preservation

Water samples collected for analysis by IC ideally should be collected in plastic containers, such as polystyrene or polypropylene bottles, as glass bottles can contribute ionic contamination when performing trace analysis.\(^{(15)}\) The bottles should be thoroughly rinsed with reagent-grade drinking-water samples.\(^{(12)}\) Table 1 details the approved conventional methods used (at the time) for the analysis of the inorganic anions commonly found in drinking water. Considering that these six individual test procedures could be replaced by one 30 min chromatographic separation, it is not surprising that IC quickly became accepted by regulatory bodies worldwide for the analysis of anions in drinking water.

\(^a\) Samples collected for oxyhalide analysis should be immediately sparged with an inert gas (e.g. nitrogen, argon, or helium) for 5 min to remove active gases such as chlorine dioxide or ozone. Samples for chlorite should be stored in amber containers.

\(^b\) EDA = ethylenediamine.

\(^c\) Eluent = 250 mM ammonium sulfate and 100 mM ammonium hydroxide.

\(^d\) Holding times can be increased by adjusting to pH 12 with sodium hydroxide.
water before use. Sample preservation requirements and holding times for anions and cations typically determined by IC are listed in Table 2.

3.2 Sample Dissolution

The majority of the water samples collected for IC analysis require little or no sample pretreatment. Drinking-water samples, for instance, typically require no pretreatment other than filtration through a 0.45 µm filter to remove particulates. Higher ionic strength water samples, e.g. wastewater, often only require dilution (and filtration) to bring the analytes of interest into the working range of the method. In fact, this so-called dilute-and-shoot approach to sample preparation is one of the advantages of IC when it comes to the practical application of this technique. However, solid samples, such as soils and sludge, are not directly amenable to IC analysis and require additional sample pretreatment.

3.2.1 Aqueous Extraction

The high solubility of ionic species in water means that such solutes can often be removed from solid samples prior to IC analysis simply by aqueous extraction of the finely divided sample. Generally, a weighed amount of the sample is mixed with a known volume of water, or other extracting solution, and homogenized using a blender or ultrasonic probe; alternatively, it is mixed with a magnetic stirrer or rotation flask. The choice of extracting solution is dependent on both the sample matrix and the nature of the solute ions. Water is preferred, in order to avoid introducing extraneous peaks into the final chromatogram. However, the following have all been used to extract ionic species from solid samples prior to IC analysis: water combined with a miscible solvent such as methanol; solutions of dilute acid or base; dilute salt solutions, such as potassium chloride or phosphate buffers; or even the eluent solution used for the IC separation. Recoveries from the aqueous extraction of solid samples for low parts per million spikes of leachable solutes, such as fluoride, chloride, bromide, and nitrate, are typically of the order of 82–101%.

3.2.2 Acid Digestion

Many solid samples, such as shale or rocks, are not amenable to simple aqueous extraction and it is necessary to digest the sample to obtain quantitative recoveries of ionic species. This is traditionally performed using concentrated acids (e.g. nitric acid) or their mixtures (e.g. nitric/hydrochloric acids) and is widely used in the preparation of environmental samples prior to analysis using spectroscopic techniques, such as AAS or ICPAES. However, acid digestion is often inappropriate for IC because the excess of the acid coanion can lead to the appearance of a large, interfering peak in the final chromatogram and can also cause column overloading. Hence, this approach is typically not employed for anion analysis, unless further sample pretreatment is being used. One important example of this approach is the determination of total cyanide by IC. Cyanide is strongly complexed to certain metals, e.g. iron, and strong acid digestion in the presence of a magnesium chloride catalyst is required to liberate free cyanide. The resulting hydrocyanic acid can be removed from the digestion matrix by reflux distillation and absorbed into a sodium hydroxide solution which can be analyzed for cyanide using IC with amperometric detection. The same approach can also be used for sulfide and fluoride in solid samples.

In general, acid digestion is better suited to preparing samples which are to be analyzed for cations using IC. For instance, total nitrogen (as the ammonium ion) has been determined in environmental samples using IC by direct analysis of the Kjeldahl digest matrix. In addition, transition metals and rare earth elements are frequently analyzed using IC with postcolumn reaction detection after acid digestion of the samples.

3.2.3 Alkali Fusion

Fusion techniques can be an attractive alternative to acid digestion for the preparation of samples of geological materials. A sample is mixed with an alkaline flux and heated at high temperatures (800–1100 °C) until the flux becomes molten. The melt is then cooled and dissolved in a suitable digestion solution prior to analysis by IC. Typical flux materials include sodium peroxide, sodium carbonate, lithium tetraborate, and sodium hydroxide. Care must again be taken to ensure that the final digest solution is compatible with the IC separation. This approach has been used for the determination of fluoride and chloride in geological materials after fusion with sodium carbonate and subsequent injection into an IC device using a carbonate/bicarbonate eluent. Occasionally, this approach is the only means available for obtaining complex samples in solution. For instance, alkali fusion followed by acid digestion proved to be necessary for the complete dissolution of mineral sands when analyzing thorium and uranium by IC with postcolumn reaction detection.

3.2.4 Combustion Methods

Sample combustion is another approach which is commonly used to prepare solid matrices for analysis by IC. This involves total combustion of the sample in oxygen, which converts nonmetallic elements to volatile gaseous
compounds. These gases can be collected into a suitable absorbing solution which can then be analyzed using IC. Combustion methods have been used for the determination of halides and total sulfur, nitrogen, and phosphorus in samples such as plant materials, silicate rocks, coal, and oil shales.\(^\text{(17)}\) The Schoeniger flask is the simplest apparatus for sample combustion. However, the oxygen pressure is limited to atmospheric pressure, which limits the sample size and ultimately the sensitivity of the analysis. Larger samples can be accommodated in a Parr bomb where oxygen pressures as high as 40 atm are used to facilitate sample combustion.\(^\text{(5)}\) The absorbing solution used for halides, which are converted to their corresponding acid gas (e.g. HCl) during combustion is typically dilute sodium hydroxide. A reducing agent, such as hydrazine sulfate, may be added to prevent the formation of oxoanions for bromide and iodide.\(^\text{(27)}\) Alternatively, sulfur and phosphorus are typically quantitated as sulfate and phosphate, respectively, hence the absorbing solution typically contains an oxidizing agent, such as hydrogen peroxide.\(^\text{(28)}\)

### 3.3 Sample Cleanup

Once a solution has been obtained it is typically necessary to perform some degree of sample pretreatment or cleanup prior to injection into the IC device. This pretreatment may be as simple as filtration, or may be a complicated time-consuming matrix-elimination step. The typical intent of sample cleanup is to achieve one or more of the following goals: (1) removal of particulates which could cause blockages or damage to the instrument; (2) reduce the overall sample loading on the column; (3) concentration or dilution of the target analytes; and (4) removal of matrix interferences.\(^\text{(5)}\)

#### 3.3.1 Filtration

As is the case with all liquid chromatographic methods, samples analyzed by IC should be free of particulates to avoid blockages or damage to connecting tubing, column end frits, and other hardware components. Samples are typically filtered through a 0.45 µm (or less) membrane-based filter. Disposable syringe filters are commercially available and their use greatly simplifies sample filtration. Also, certain types of autoinjectors will automatically filter the sample before injection into the IC instrument. However, the possibility of sample contamination from these devices can be a concern, particularly when performing trace analysis. Rinsing filters with 20 mL of deionized water prior to filtration of the sample has been shown to remove most inorganic contaminants.\(^\text{(29)}\)

#### 3.3.2 Matrix Elimination

Complex aqueous samples, such as wastewaters and solid leachates, often require further chemical modification (cleanup) of the sample in order to eliminate matrix interferences. Solid-phase extraction (SPE) cartridges represent the most convenient means of removing interferences prior to ion chromatographic analysis.\(^\text{(30)}\) These commercially available disposable cartridges enable rapid sample pretreatment and require only small volumes of sample. SPE cartridges are available with many different chromatographic packing materials; including silica, alumina, C\(_{18}\), anion-exchange resins (OH\(^-\) form), cation-exchange resins (H\(^+\), Ag\(^+\), Ba\(^+\) forms), neutral polymer, amino, and activated carbon.\(^\text{(5)}\) These cartridges can be employed in a number of different modes of operation with IC analyses, as discussed below.

- Hydrophobic SPE cartridges, e.g. C\(_{18}\) and neutral polymers, can be used to remove neutral organic compounds, while allowing inorganic ions to pass through unretained. Hydrophobic organic compounds do not typically interfere during an IC separation; however, they can be strongly retained on the stationary phase material which can lead to decreased column lifetimes. This approach is typically required when using IC for the analysis of ions in food and biological matrices, or wastewaters and soil leachates containing high levels of organics, e.g. humic acids.\(^\text{(17,21)}\)

- Cation- and anion-exchange SPE cartridges in the H\(^+\) and OH\(^-\) forms, respectively, can be used to adjust sample pH and reduce total ionic strength without adding a potentially interfering coanion (for acids) or cocation (for bases) to the sample.\(^\text{(30)}\)

- Cation-exchange SPE cartridges in the H\(^+\) form can be used to remove carbonate and cationic species, such as iron\(^{III}\) and aluminum, which may precipitate under alkaline eluent conditions.\(^\text{(17)}\) Cation-exchange cartridges in the Ag\(^+\) and Ba\(^+\) forms can be used to selectively remove halides and sulfate from samples by precipitating insoluble silver halides or barium sulfate, respectively.\(^\text{(30)}\) The Ag\(^+\) form cartridges are widely used to selectively remove chloride from environmental waters to allow trace analysis of anions, such as bromate in ozonated waters, which would otherwise be masked by the excess chloride.\(^\text{(31)}\)

Recently, SPE disks have become available as an alternative to the cartridge configuration. These disks are available with many of the same packings as the cartridges, although their geometry allows the use of higher sample loading flow rates.\(^\text{(32)}\) The use of dialysis across membranes offers another means of reducing sample interferences, and this approach has been used...
to reduce sample acidity,\(^{(33)}\) basicity,\(^{(34)}\) and also chloride in brine samples prior to IC analysis.\(^{(35)}\)

### 3.3.3 On-line Matrix Elimination

Many of the sample preparation techniques described above can also be performed using on-line instrumentation. This approach offers the benefits of greater precision and the process can often be automated, although the instrumentation is usually more complex. The most common application of on-line matrix elimination in IC is sample preconcentration. A measured volume of sample is first passed through an ion-exchange concentrator column and the solute ions are retained on this column, while the bulk sample solution (i.e. water) passes through to waste. The concentrator column is then switched to be in line with the eluent, which carries the solute ions through to the analytical column to be separated and detected in the usual manner.\(^{(5)}\) This approach is frequently used for the determination of trace ions in high-purity waters, e.g. steam and boiler feed water for power station generators.\(^{(36)}\)

Sample preconcentration can also be successfully applied to high-ionic-strength samples, particularly if the solutes of interest are strongly retained on the concentrator column. The strongly retained solutes can be trapped on the concentrator column while weakly retained solutes and water pass through to waste. This approach, which effectively combines sample preconcentration with matrix elimination, has been used for the determination of anions in aqueous vegetation extracts and low parts per billion levels of precious metal cyanide complexes in gold tailings solutions.\(^{(37,38)}\) A variation on using ion-exchange columns to selectively concentrate ionic solutes prior to IC analysis is the use of chelating resins. These materials can be used to selectively complex transition metal and rare earth elements in the presence of high levels of alkali and alkaline earth metals. This approach has been employed for the on-line cleanup and concentration of low parts per billion levels of transition metals and lanthanides in complex geological matrices and seawater prior to analysis by IC or ICPMS.\(^{(39)}\)

Automated matrix elimination can also be performed using heart-cut techniques. This involves loading the sample onto a short column, then carefully switching only the fraction of eluent containing the solute(s) of interest towards the separator column. This approach, which typically performs best when the sample matrix has a consistent composition, has been used for the determination of trace anions in samples containing high levels of chloride.\(^{(50)}\)

### 4 REGULATORY METHODS OF ANALYSIS

IC has been approved by many standard or regulatory organizations in numerous countries for the analysis of

both anions and cations in environmental samples. The majority of the approved methods are for the analysis of anionic solutes; however, some approved methods exist for cations. Although a complete listing of approved IC methods worldwide is beyond the scope of this article, a list of the most important regulatory IC methods used for environmental water and waste analysis in the USA is given in Table 3.\(^{(40)}\)

Many different regulatory agencies promulgate what are essentially similar methods, as Table 3 illustrates. For instance, ASTM D 4327-97 uses the same methodology as USEPA Method 300.0(A); however, each agency has a unique method format and writing style. Also, differences exist between the methods in the area of quality control (QC). Thus QC is mandated in most USEPA methods whereas it is currently optional in ASTM methods. Different regulatory agencies exist even within the USEPA; hence Method 300.0 is applicable to the analysis of inorganic anions in drinking water and wastewater under direction of the Office of Groundwater and Drinking Water, whereas Method 9056 is applicable to the analysis of inorganic anions in all water types and combustion bomb extracts under direction of the Office of Solid Waste and Emergency Response.

In addition to the methods shown in Table 3 which use IC for environmental water and waste analysis, a considerable number of IC methods are employed for air analysis. Regulatory bodies, such as the National Institute of Occupational Safety and Health (NIOSH) and the Occupational Safety and Health Administration (OSHA), specify IC for the analysis of compounds in air and workplace atmospheres that form ionic species in solution (e.g. formic acid, sulfur dioxide, nitrous oxides, ammonia, and hexavalent chromium).

Although Table 3 details only methods approved in the USA, many industrial countries around the world have similar health and environmental standards; consequently, a considerable number of regulatory IC methods exist worldwide. For instance, German Methods DIN 38 405 (D 20) and DIN ISO (International Organization for Standardization) 10 304-1 are similar to USEPA Method 300.0, whereas DIN 38 405 (D 22) is applicable to the determination of chromate, iodide, sulfate, thiocyanate, and thiosulfate in water matrices. French Method AFNOR T90-042 is again similar to EPA Method 300.0, as is the Italian method UNICHIM 926 (1991). Several IC methods are approved in Japan for the analysis of anions in matrices, such as industrial waters (K0101), industrial wastewater (K0102), mine water, and wastewater (M0202).\(^{(41)}\) Japan also has a method detailing general rules for IC analysis (K0127), whereas Standards Australia has a recommended practice for chemical analysis by IC (AS 3741-1990).\(^{(42)}\)

## 5 WATER AND WASTEWATER ANALYSIS

### 5.1 Drinking Water and Wastewater

Water quality in the USA is legislated through the Safe Drinking Water Act (SDWA) and the Clean Water Act (CWA). The SDWA ensures the integrity and safety of US drinking water, whereas the goal of the CWA is to reduce the discharge of pollutants into US waters. The majority of the regulatory methods of analysis that use IC are validated for both drinking water and wastewater, hence these matrices will be considered together.

#### 5.1.1 Common Inorganic Anions

The US National Primary Drinking Water Standards specifies a maximum contaminant level (MCL) for a number of common inorganic anions, including fluoride, nitrite, and nitrate. The MCLs are specified to minimize potential health effects arising from the ingestion of these anions in drinking water. For instance, high levels of fluoride causes skeletal and dental fluorosis, whereas nitrite and nitrate can cause methemoglobinemia, which can be fatal to infants.\(^{(21)}\) Consequently, the analysis of these anions in drinking waters is mandated, as are the analytical methods used for their quantification. Other common anions, such as chloride and sulfate, are considered secondary contaminants. The Secondary Drinking Water Standards are guidelines regarding taste, odor, color and certain aesthetic effects that are not federally enforced. However, they are recommended to all states as reasonable goals and many of the states adopt their own enforceable regulations governing these contaminants.\(^{(43)}\)

IC has been approved for compliance monitoring of these common inorganic anions in drinking water in the USA since the mid-1980s, as described in EPA Method 300.0. This same method received interim approval for the analysis of inorganic anions in wastewater under the National Pollution Discharge Elimination System (NPDES) permits program in 1992. Method 300.0 specifies the use of a Dionex\textsuperscript{®} AS4A anion-exchange column with an eluent of 1.7 mM sodium bicarbonate/1.8 mM sodium carbonate for the separation of common anions. An optional column may be substituted provided comparable resolution of peaks is obtained and that the QC requirements of the method can be met.\(^{(22)}\) Conductivity detection is used for quantification after suppression of the eluent conductance with an anion micro-membrane suppressor (AMMS) or similar device.

Figure 1 shows a chromatogram of a standard containing low parts per million levels of common anions obtained using the conditions described in Method 300.0. All the anions are well-resolved within a total run time of less than 8 min. The application range and MDLs that can be achieved for each of the anions using...

Method 300.0 are shown in Table 4. Similar methods, such as ASTM D 4327-97 and Standard Methods 4110, provide comparable performance. Advances in column and suppressor technology continues to improve the methodology for determination of these common anions. The IonPac® AS14 column provides complete resolution of fluoride and acetate and also improved resolution of fluoride from the void peak compared to the AS4A column. Figure 2 shows a chromatogram of a typical drinking-water sample obtained using an AS14 column with a 3.5 mM bicarbonate/1.0 mM carbonate eluent and suppressed conductivity detection.

EPA Method 300.0 is also validated for wastewater analysis, although such samples often require sample pretreatment before injection into the ion chromatograph. Dilution into the application range followed by filtration is often required, whereas pretreatment with SPE cartridges to remove hydrophobic organic material is recommended to prolong column lifetimes. Figure 3 shows a chromatogram of a typical domestic wastewater sample obtained using an AS4A column with a carbonate/bicarbonate eluent and suppressed conductivity detection. The performance of environmental methods, such as EPA Method 300.0, is typically validated through single- and multioperator precision and bias studies on spiked samples. Table 5 shows single-operator precision and bias data obtained using Method 300.0 for common anions spiked into reagent water, drinking water, and mixed domestic and industrial wastewaters. Acceptable precision and bias data were obtained for the determination of common anions in all three matrix types when using IC.
rule. drinking water, which was promulgated in Stage I of USEPA has proposed an MCL for bromate of 10^1 µg L^-1, equivalent to 1 in 10^4 for a lifetime exposure to drinking water containing bromate at 5 µg L^-1.

The occurrence of bromate and other DBPs in US drinking water has recently been documented by the USEPA through the comprehensive collection of data mandated by the information collection rule (ICR). The USEPA recently developed Method 300.1 for the determination of inorganic and DBP anions. Method 300.1 specifies a Dionex® AS9-HC anion exchange column with a 9.0 mM sodium carbonate eluent and suppressed conductivity detection. The AS9-HC differs from the column specified in Method 300.0(B) in that it has higher capacity and improved separation of the key oxyhalide anions from potential interferences. Method 300.1(A) is applicable to common inorganic anions in drinking water, whereas 300.1(B) is applicable to the determination of DBP anions, and bromide, in drinking water. Methods 300.1(A) and (B) use different injection volumes to achieve different MDLs. Method 300.1(A) requires 10 µL whereas 300.1(B) requires 50 µL when using a 2 mm ID (internal diameter) column, or 50 µL and 200 µL injections, respectively, with a 4 mm ID column. The relatively large injection volume is required for 300.1(B) in order to achieve the DLs necessary when analyzing DBP anions.

Figure 4 shows the separation of chlorite, bromate, and chloride, in addition to the common inorganic anions using an AS9-HC column. The MDLs for 300.1(B) using a 50 µL injection and 2 mm ID column are 0.89, 1.44, 1.44, and 1.31 µg L^-1 for chloride, bromate, and nitrite, respectively. Method 300.1(B) use different injection volumes to achieve different MDLs. Method 300.1(A) requires 10 µL whereas 300.1(B) requires 50 µL when using a 2 mm ID (internal diameter) column, or 50 µL and 200 µL injections, respectively, with a 4 mm ID column. The relatively large injection volume is required for 300.1(B) in order to achieve the DLs necessary when analyzing DBP anions.

### 5.1.2 Disinfection By-product Anions

USEPA Method 300.0 was revised in 1993 to include determination of the disinfection by-product (DBP) anions – bromate, chlorite, and chlorate. Bromate is a DBP produced from the ozonation of source water that contains naturally occurring bromide, whereas chlorite and chlorate are produced as a result of using chlorine dioxide as a disinfectant. These DBP anions pose significant health risks, even at low microgram per liter levels. Bromate has been judged as a potential carcinogen and the USEPA has estimated a potential cancer risk equivalent to 1 in 10^4 for a lifetime exposure to drinking water containing bromate at 5 µg L^-1.  

The occurrence of bromate and other DBPs in US drinking water has recently been documented by the USEPA through the comprehensive collection of data mandated by the information collection rule (ICR). The USEPA has proposed an MCL for bromate of 10 µg L^-1 and an MCL for chlorite of 1000 µg L^-1 in finished drinking water, which was promulgated in Stage I of the disinfectant and disinfection by-product (D/DBP) rule. USEPA Method 300.0(B) specifies the use of a Dionex® AS9-SC anion-exchange column with a 1.7 mM sodium bicarbonate/1.8 mM sodium carbonate eluent and suppressed conductivity detection for the analysis of bromate, chlorite, and chlorate. However, Method 300.0(B), as originally published, cannot meet the quantitation requirements of the ICR and method modifications are required. These include the use of a weaker borate eluent to improve bromate and chloride resolution and the use of sample pretreatment to minimize chloride interference.

In support of the publication of Stage I of the D/DBP rule, the USEPA recently developed Method 300.1 for the determination of inorganic and DBP anions. Method 300.1 specifies a Dionex® AS9-HC anion exchange column with a 9.0 mM sodium carbonate eluent and suppressed conductivity detection. The AS9-HC differs from the column specified in Method 300.0(B) in that it has higher capacity and improved separation of the key oxyhalide anions from potential interferences. Method 300.1(A) is applicable to common inorganic anions in drinking water, whereas 300.1(B) is applicable to the determination of DBP anions, and bromide, in drinking water. Methods 300.1(A) and (B) use different injection volumes to achieve different MDLs. Method 300.1(A) requires 10 µL whereas 300.1(B) requires 50 µL when using a 2 mm ID (internal diameter) column, or 50 µL and 200 µL injections, respectively, with a 4 mm ID column. The relatively large injection volume is required for 300.1(B) in order to achieve the DLs necessary when analyzing DBP anions.

Figure 4 shows the separation of chlorite, bromate, and chloride, in addition to the common inorganic anions using an AS9-HC column. The MDLs for 300.1(B) using a 50 µL injection and 2 mm ID column are 0.89, 1.44, 1.44, and 1.31 µg L^-1 for chloride, bromate,
Figure 5 Determination of low-level oxyhalides and common anions in simulated drinking water. Conditions as for Figure 4, except: injection volume, 200 µL; solutes, 1 = fluoride (1 mg L⁻¹), 2 = chlorite (0.01 g L⁻¹), 3 = bromate (0.005 mg L⁻¹), 4 = chloride (50 mg L⁻¹), 5 = nitrite (0.1 mg L⁻¹), 6 = bromide (0.01 mg L⁻¹), 7 = chlorate (0.01 mg L⁻¹), 8 = nitrate (10 mg L⁻¹), 9 = phosphate (0.1 mg L⁻¹), 10 = sulfate (50 mg L⁻¹).

bromide, and chlorate respectively. Figure 5 shows the chromatogram of a synthetic drinking water sample obtained using an AS9-HC column with a 9.0 mM carbonate eluent and suppressed conductivity detection. Despite using a 200 µL injection, no column overloading occurs and bromate can be determined at 5 µgL⁻¹ in the presence of a 10 000-fold excess of chloride. Figure 6 shows the application of Method 300.1(B) to the determination of DBP anions in drinking water from Sunnyvale, California. The water in this municipality is disinfected using hypochlorite, hence chlorate appears in the drinking water matrix, shown in Figure 6(a). The same drinking water spiked with 10 µg L⁻¹ each of chlorite, bromate, bromide, and chloride is shown in Figure 6(b), indicating that the DBP anions are clearly resolved from the common inorganic anions (and bromide) present in drinking water. Table 6 shows single-operator precision and bias data obtained using Method 300.1 for the DBP anions spiked into reagent water, drinking water, and high-ionic-strength drinking water.

5.1.3 Hexavalent Chromium

USEPA Methods 300.0 and 300.1, and equivalent methods in the USA and other countries, represent the most important and widely used applications of IC in environmental analysis. However, a number of other regulatory methods based on IC are applicable to drinking-water and wastewater analysis. Inorganic chromium is a primary drinking-water contaminant with an MCL of 0.1 mg L⁻¹. Hexavalent chromium is the most toxic form of the metal,
in addition to being a suspected carcinogen. Hexavalent chromium can be separated as the chromate anion using a high capacity Dionex® AS7 anion-exchange column, as specified in USEPA Method 218.6. In this case, detection is achieved using a UV/VIS detector after postcolumn reaction with diphenylcarbohydrazide, as this color-forming reagent provides a more sensitive and selective means for determining chromate than suppressed conductivity. USEPA Method 218.6 and ASTM D 5257-93 are validated for the determination of hexavalent chromium in drinking water, groundwaters and industrial wastewaters. An MDL of 0.3 µg L\(^{-1}\) for Cr(VI) in drinking and wastewater can be achieved using a 250 µL injection. Average recoveries in the order of 98–105% were obtained for 100 µg L\(^{-1}\) Cr(VI) solutions spiked into reagent, drinking, ground, primary sewage waste and electroplating wastewaters. Figure 7 shows a chromatogram of a spiked wastewater sample obtained using the conditions described in USEPA Method 218.6. No interfering peaks are observed when using this very specific detection approach for Cr(VI) analysis.

5.1.4 Cyanide

The highly toxic cyanide anion is a primary drinking-water contaminant which has an MCL of 0.2 mg L\(^{-1}\). Sources of cyanide contamination in drinking water include effluents from the electroplating, steel, plastics and mining industries, in addition to certain fertilizers. Cyanide is classified according to its availability in the presence of complexing metals. Total cyanide refers to CN that can be released as hydrocyanic acid (HCN) from both the aqueous and particulate portions of a sample under total reflux distillation conditions and includes both free and complex cyanides. Free cyanide refers to CN that can be released as hydrocyanic acid from the aqueous portion of a sample by direct cyanide determination without reflux distillation. Cyanide amenable to chlorination refers to CN determined after chlorinating a portion of sample, and calculating the difference between total cyanide in the original and chlorinated samples. Weak acid dissociable cyanide refers to CN determined after distillation with a weak acid. This only releases CN bound in weak complexes, i.e., those with low stability constants, such as with Cu or Zn. In practice, the majority of CN determinations, particularly in wastewater samples, involve measurement of total CN, which is determined after reflux distillation of an alkaline sample in the presence of sulfuric acid and a magnesium chloride catalyst. The released HCN is absorbed into a sodium hydroxide scrubber solution and the cyanide in this solution can be measured colorimetrically, by IC, FIA, titration, or ISE. An IC separation is recommended with electrochemical detection when sulfur, thiocyanate, or other sulfur-containing compounds are present in the sample, as H\(_2\)S codistills with HCN and can interfere with the FIA determination when using electrochemical detection.

ASTM D 2036-97 is validated for the determination of total cyanide in drinking, ground, and surface waters, and both domestic and industrial wastes using IC, in addition to other analytical measurement techniques. Cyanide is separated on a Dionex® AS7 anion-exchange column using an eluent of 100 mM sodium hydroxide/500 mM sodium acetate/0.5% (V/V) ethylenediamine. The CN is then detected using an amperometric detector with a silver working electrode operated at −0.05 V. This very sensitive detection approach provides an MDL of 2 µg L\(^{-1}\) when using a 1.0 mL injection volume and can tolerate sulfur concentrations up to 100 times the cyanide level without degradation of method performance. Figure 8 shows a chromatogram of cyanide and sulfate in a spiked wastewater sample obtained using an AS7 column and amperometric detection. The applicable range of this method is from 10 µg L\(^{-1}\) to 10 mg L\(^{-1}\) cyanide; mean recoveries in the order of 85–98% were obtained for samples spiked with CN over the range 40–1000µg L\(^{-1}\).

5.1.5 Perchlorate

Ammonium perchlorate is a key ingredient in solid rocket propellants which has recently been found in groundwaters in regions of the USA where aerospace
material, munitions, and fireworks have been developed, tested, or manufactured. Perchlorate has been found in ground and surface waters in California, Nevada, Utah, and West Virginia. Perchlorate poses a human health risk and preliminary data from the USEPA reports that exposure to less than 4–18 µg L⁻¹ as providing adequate health protection. Perchlorate is listed on the USEPA contaminant candidate list as a research priority, although it is not currently regulated under the Federal SDWA. Perchlorate contamination of public drinking-water wells is becoming a serious problem in some western States and the California Department of Health Services (CDHS) has adopted an action level for perchlorate in drinking water of 18 µg L⁻¹. To date, perchlorate has been detected in over 100 public drinking-water wells in California, with more than 20 wells being closed due to contamination.

The CDHS developed an IC method based on the use of an hydrophilic IonPac® AS5 column, large loop injection, and suppressed conductivity detection to quantify perchlorate at low microgram per liter levels. However, the use of an IonPac® AS11 column with an eluent of 100 mM hydroxide, 1000 µL injection, and suppressed conductivity detection provides an MDL for perchlorate of 0.3 µg L⁻¹ without the need for an organic modifier in the mobile phase. Figure 9 shows a chromatogram of perchlorate standard at 20 µg L⁻¹, whereas Figure 10 shows a drinking water sample spiked with 6.0 µg L⁻¹ perchlorate. The applicable range of this method is from 2.0 to 100 µg L⁻¹ perchlorate. The method is free of interferences from common anions and quantitative recoveries were obtained for low microgram per liter levels of perchlorate in spiked drinking and groundwater samples.

5.1.6 Inorganic Cations and Ammonia

The preceding discussion shows that a number of regulatory methods based on IC are available for anion analysis; however, that is not case for cation analysis. The majority of the inorganic cations listed as primary drinking water contaminants are transition metals which are most commonly analyzed using spectroscopic methods, such as AAS, ICPAES, or ICPMS. However, IC is a USEPA-approved method for the analysis of the ammonium cation, sodium, potassium, calcium, and magnesium.
in rain water and wet precipitation, and provides a straightforward method for the simultaneous analysis of these cations.\(^{19}\) Also, the ISO has recently published an ISO Method for the simultaneous determination of dissolved alkali and alkaline earth cations, ammonia, and manganese in water and wastewater using IC.\(^{51}\) Figure 11 shows an example of a typical separation of alkali and alkaline earth cations and ammonia obtained using a Dionex® CS12A column with an eluent of methanesulfonic acid and suppressed conductivity detection.

IC is particularly beneficial for the simultaneous determination of cations plus ammonia in wastewaters containing amines, as these compounds can interfere with the conventional colorimetric or ISE methods used for ammonia analysis. Recently, an ASTM method based on IC has been proposed for the analysis of ammonia, sodium, potassium, calcium, and magnesium in reagent, drinking, surface, and groundwater and mixed industrial and domestic wastewater. This method uses a Dionex® CS15 column which has crown ether functionalities incorporated into the stationary phase to provide maximum resolution of ammonia and the adjacent sodium peak. The use of this column with an eluent of 13 mM sulfuric acid and suppressed conductivity detection can achieve an MDL for ammonia of 1.0 \(\mu \text{g L}^{-1}\) using a 100 \(\mu \text{L}\) injection loop.\(^{52}\) Figure 12 shows the application of this column for the determination of ammonia in industrial wastewater containing a large excess of sodium.

### 5.2 Natural Waters

In addition to being approved for a number of drinking-water and wastewater analyses, IC is also widely used for analysis of natural water samples. Many of the regulatory methods described in section 5.1 are also validated for natural waters, such as ground and surface waters. Natural waters encompass a wide variety of sample matrices, including: rain and acid rain; mineral spring waters and other groundwaters; surface waters (such as river, stream, lake, and pond waters); soil pore waters; runoff waters; snow, hail, and sleet; ice and ice cores; well and bore waters, etc. There are few regulations governing the analysis of such samples, hence a great diversity of IC methods are applied to a much wider range of analytes than in the highly regulated area of drinking water and wastewater analysis.

Although the key regulatory methods which use IC were described in the preceding pages, it is beyond the scope of this article to describe all of the applications of IC to natural-water analysis. Good overviews of the early use of IC for environmental applications are available,\(^{9,10}\) and two very comprehensive listings of environmental analyses using IC were published in
In addition, proceedings of the International IC Symposium, published annually since 1991 by the Journal of Chromatography, contain excellent summaries of current developments and applications of IC for environmental and other analyses.

The analysis of rain water and acid rain is one of the more important applications of IC. The determination of ionic components in rain waters by IC is frequently used to estimate the effects of acidification on the natural and urban environments caused by acid rain. The major ionic components of acid rain consist of the hydronium ion, sodium, ammonium, potassium, calcium, magnesium, and chloride, nitrate, and sulfate. Clearly, separate analyses using the separations presented in Figures 1 and 11 would provide the major components of an ion balance for an acid rain, once the sample pH had been measured. USEPA Methods 300.7 and 300.6 are based on similar, although somewhat dated, methods for the determination of these cations and anions, respectively, in acid rain and rain water.

Many researchers have developed methods that enable the simultaneous determination of both anions and cations in rain waters and atmospheric aerosols, with perhaps the most comprehensive approach involving an automated quadruple IC system to perform isocratic anion, gradient anion (with and without sample pre-concentration), and gradient cation separations using a single sample injection. Tanaka et al. developed a less complex approach that enables the simultaneous determination of anions and cations in acid rain based upon a simultaneous ion-exclusion–cation-exchange separation and non-suppressed conductimetric detection. Figure 13 shows an example of a chromatogram of anions and cations in rain water obtained using this approach.

Gradient elution is typically required to quantify all of the minor acid components of rain-water samples, as organic acid anions, such as formate, acetate, or methanesulfonate, are often present at low levels in rain-water samples. Figure 14 shows an example of the resolving power that can be achieved with an hydroxide gradient using modern IC instrumentation, whereas Figure 15 shows the separation of inorganic anions and organic acids in rain water obtained using a borate gradient with a Dionex AS11 column and suppressed conductivity detection. Gradient separations can be used to quantify a wide range of anionic solutes in complex water samples, such as hazardous-waste leachates. In addition to rain-water analysis, IC has also been used to analyze terrestrial waters and ice cores from pristine environments, such as Antarctica, in order to establish baseline levels of pollutants.

The analysis of ground and surface waters is another common application of IC. The determination of inorganic solutes in waters from rivers, streams, lakes, and ponds is similar in complexity to the analysis of typical wastewater samples. Filtration followed by pretreatment with SPE cartridges to remove hydrophobic organic material is recommended when analyzing most ground and surface waters. Mineral waters are typical examples of natural groundwaters which are commonly analyzed by IC. These samples can significantly differ in both total mineralization and also chemical composition. IC has been shown to be applicable to the determination of over 98.6% of the total cation composition and over 98.9% of the noncarbonate anion composition of mineral waters. Similarly, IC is also frequently applied to the determination of inorganic ions in surface waters. Figure 16 shows the analysis of inorganic anions in lake water from Salt Lake in Utah obtained using an AS4A column and suppressed conductivity detection.

IC tends to be more commonly utilized for the determination of metal species in natural waters than in drinking-water and wastewater samples. The ability of IC to quantify different oxidation states, such as Fe(II) or Fe(III); and stable metal complexes, such as metallocyanides, or both inorganic and organic arsenic species is of great benefit in determining the fate, transport, and toxicity of metals in natural waters. Figure 17 shows an example of the determination of low parts per billion levels of metal cations in

Figure 13 Simultaneous determination of anions and cations in acid rain. Conditions: column, Tosoh TSKgel OA-PAK; eluent, 5 mM tartaric acid/7.5% methanol; flow rate, 1.2 mL min⁻¹; detection, nonsuppressed conductivity; injection volume, 100 µL; sample, acid rain from Nagoya, Japan; solutes, 1 = sulfate, 2 = chloride, 3 = nitrate, 4 = sodium, 5 = ammonia, 6 = potassium, 7 = magnesium, 8 = calcium. (Reprinted from K. Tanaka, K. Ohta, J.S. Fritz, S. Matsushita, A. Miyanaga, ‘Simultaneous Ion-exclusion Chromatography Cation Exchange Chromatography with Conductometric Detection of Anions and Cations in Acid Rain Waters’, J. Chromatogr., 671, 239–248, Copyright (1994) with permission from Elsevier Science.)
addition to the use of conventional suppressed IC, other waters has recently been reviewed by Singh et al. of anions in high salt concentration environmental these minor components. The use of IC for the analysis of a variety of approaches have been used for the analysis of the careful selection of analytical conditions, and a wide analysis of minor components in brines typically requires before direct injection into the IC device. is relatively straightforward, only requiring a dilution of major components, e.g. chloride and sulfate, in brines, and very high salinity groundwaters. The analysis which include seawater, subsurface brines, geothermal analysis of inorganic solutes in natural-water brines, sample. Nevertheless, IC is frequently used for the high ionic strength and excess sodium chloride in the The analysis of brines by IC is complicated by the river water obtained after preconcentrating 40 mL of sample. 5.3 Brines The analysis of brines by IC is complicated by the high ionic strength and excess sodium chloride in the sample. Nevertheless, IC is frequently used for the analysis of inorganic solutes in natural-water brines, which include seawater, subsurface brines, geothermal brines, and very high salinity groundwaters. The analysis of major components, e.g. chloride and sulfate, in brines is relatively straightforward, only requiring a dilution before direct injection into the IC device. However, the analysis of minor components in brines typically requires careful selection of analytical conditions, and a wide variety of approaches have been used for the analysis of these minor components. The use of IC for the analysis of anions in high salt concentration environmental waters has recently been reviewed by Singh et al. In addition to the use of conventional suppressed IC, other approaches include: using sodium chloride as the eluent; sample pretreatment with Ag-form membranes and SPE cartridges; the use of heart-cut matrix elimination or preconcentration combined with matrix elimination; and the use of more selective detection methods, such as UV/VIS absorption, amperometry, postcolumn derivatization, and even ICPMS.

The use of sodium chloride as an eluent combined with low-wavelength UV detection allows the determination of UV-absorbing anions, such as nitrate, iodide, and molybdate, in samples containing up to 20000 mg L\(^{-1}\) of chloride without loss of chromatographic performance. A similar approach with an eluent containing chloride and an ion-pairing reagent has been used for the analysis of thiosulfate and polythionates in natural saline waters. Sample pretreatment with Ag-form SPE cartridges or membranes to reduce chloride is a commonly used approach to allow determination of minor anionic components in brines. Chloride precipitates as AgCl, although other halides are also removed to a significant extent using this approach and poor recoveries can

Conditions as for Figure 3, except: sample, water from Salt Lake, Utah; solutes, 1 = injection peak, 2 = fluoride (0.28 mg L⁻¹), 3 = chloride (142 mg L⁻¹), 4 = bromide (0.18 mg L⁻¹), 5 = nitrate (11.2 mg L⁻¹), 6 = phosphate (0.28 mg L⁻¹), 7 = sulfate (44 mg L⁻¹).

be obtained for nitrite. Selective detection can be applied to the determination of specific ions; for instance, iodide has been determined in brine using pulsed amperometry at a silver working electrode after separation on a Dionex® AS11 column with an eluent of 50 mM nitric acid. Iodide could be quantified at 16 µg L⁻¹ in 30% NaCl after a 10-fold dilution and calibration using standard addition.

Automated matrix elimination techniques have also been used to determine anions and metals in seawater samples. Nitrite, bromide, nitrate, and sulfate have been determined in brine using a heart-cut and recycling system. A unresolved cut of the sample containing

chloride and nitrite is trapped in a sample loop and re-injected onto an anion-exchange column using four- and six-port switching valves. This method permits a DL of 0.5 mg L\(^{-1}\) for nitrite in spiked seawater samples when using IC with suppressed conductivity detection.\(^{70}\) The use of a highly cross-linked, iminodiacetate functionalized macroporous resin has been shown to selectively retain transition metals and lanthanides in the presence of high levels of alkali and alkaline earth metals.\(^{71}\) A Dionex\textsuperscript{8} MetPac\textsuperscript{®} CC-1 chelating concentrator has been used to concentrate transition metals from seawater, after which the metals are eluted, via an intermediate cation exchange concentrator, to a CS5 analytical column with a pyridine 2,6-dicarboxylic acid eluent. The separated metals were detected using UV/VIS absorption after postcolumn derivatization with PAR. A chromatogram obtained using this approach for the determination of transition metals in seawater is shown in Figure 18; a similar approach has also been used for the analysis of uranium and thorium in seawater.\(^{72}\)

6 SOIL, SLUDGE, AND SOLID WASTE ANALYSIS

6.1 Soil and Soil Extracts

The analysis of inorganic ions in soils was amongst the earliest applications of IC.\(^{9,10}\) As is also the case with natural waters, the ability of IC to quantify different metal oxidation states and stable metal complexes in soil extracts is beneficial in determining the fate, transport and toxicity of metals in soil.\(^{14,62}\) Also, the analysis of total nitrogen, phosphorus, and sulfur, and their corresponding oxide anions, e.g. nitrite, nitrate, phosphate, and sulfate, is of importance in assessing soil condition and fertility. Ideally, solutions injected for IC analysis should be low in organic materials, strong acids, and soluble salts; hence, many of the traditional methods used for the extraction or digestion of soils are not compatible with IC.\(^{73}\) However, modifications of traditional extraction methods, including the use of water or more dilute salt solutions, have now been developed to allow the application of IC to soil analysis. In fact, a wide variety of extraction and dissolution conditions have now been used for soil samples prior to IC analysis. Table 7 gives examples of species which have been determined in soils by IC, and typical extraction and dissolution conditions used for sample preparation. The extraction process generally involves forming a slurry of a dried soil sample with approximately 10 times its mass of extracting solution. The slurry is then mixed using a suitable mechanical device, such as a rotation apparatus, wrist shaker, or sonic bath, for a period anywhere from 10 min to 24 h depending upon the sample.\(^{17}\) The slurry is then centrifuged, filtered, pretreated using SPE if necessary, and injected into the ion chromatograph. Figure 19 shows an example of the determination of anions in an aqueous extract of a fertilized soil sample.

Alkali and alkaline earth cations can simply be extracted from soils using a dilute mineral acid.\(^{73}\) However, transition metals are typically bound to complexing agents in soils and require more severe extraction conditions or total digestion of the sample. Metals, such as Cd, Cu, Mn, or Zn, have been determined in soils after

Although IC is most commonly applied to the analysis of soil samples. Samples such as sludges, landfill, and solid (or hazardous) wastes are typically leached under aqueous conditions, then filtered and pretreated using SPE if necessary prior to injection. Although IC is most commonly applied to the analysis of inorganic ions in sludge, leachates, and similar solid wastes by IC is similar in practice to the quantitation of metals in sludges and solid wastes.

Total metals have been determined in sewage sludges and Fe(II), have been analyzed in tannery sludges after digestion in mixed nitric, perchloric, and hydrofluoric acids, followed by extraction using dithizone in chloroform, and destruction of the metal–dithizonate complex in nitric acid. The metals were chromatographed using a CS5 analytical column with a pyridine 2,6-dicarboxylic acid eluent and detected using UV/VIS absorption after postcolumn derivatization with PAR. In some circumstances, metals can be released from soils using simple extraction procedures. The microbial reduction of Fe(III) to Fe(II) in soils and sediments is an important geochemical process and both hydrochloric acid (0.5 M) and ammonium oxalate (0.36 M) have been used to extract ferrous and ferric ions from these samples prior to IC analysis. Figure 20 shows a chromatogram of Fe(III) and Fe(II) in a 0.5 M HCl extract of a soil sample.

6.2 Sludge, Leachates, and Solid Waste

Figure 20 Determination of ferric and ferrous ions extracted from soil with 0.5 M HCl. Conditions as for Figure 18 except: eluent, 6 mM pyridine 2,6-dicarboxylic acid/50 mM acetic acid/50 mM sodium acetate; sample, 0.5 M HCl (1:10) soil extract; solutes, Fe(III) at 375 µM, Fe(II) at 239 µM. (Reprinted from M.Y. Ye, Y. Shen, C.C. West, W.G. Lyon, (1977) 551–565 by courtesy of Marcel Dekker Inc.)

The quantitation of metals in sludges and solid wastes also requires more severe extraction conditions or digestion of the sample, as is the case with soil samples. Total metals have been determined in sewage sludges by IC after dissolution in mixed nitric, perchloric, and hydrofluoric acids, followed by extraction using dithizone in chloroform, and destruction of the metal–dithizonate complex in nitric acid. The metals were then chromatographed using a CS5 cation-exchange column and detected using UV/VIS absorption after postcolumn derivatization with PAR. Metals, such as Cr(III), Al(III), and Fe(II), have been analyzed in tannery sludges after extraction with sulfuric acid. The dried sludge samples were contacted for 24 h in concentrated sulfuric acid (1:20 ratio), then filtered, diluted, and passed through
Sludges and solid-waste samples can also be prepared for analysis by IC using combustion methods. USEPA Method 9056 is applicable to the determination of common inorganic anions in solid-waste combustion extracts. The weighed sample is placed in a sample cup and combusted in a Parr bomb containing oxygen under pressure. Released acid gases are trapped in a dilute carbonate/bicarbonate solution which can be analyzed for anions using an anion-exchange column with a carbonate/bicarbonate eluent and suppressed conductivity detection. The method is applicable to the determination of anions at levels greater than 500 mg L\(^{-1}\) in solid wastes, virgin and used fuel oils, fuels, and related materials.\(^{23}\)

### 7 QUALITY ASSURANCE

QC is an essential part of environmental analysis when it comes to generating reliable results using IC, or any analytical method. A great deal of literature is available in the area of quality management and the subject of QC in environmental analysis is covered in detail in the article Quality Assurance in Environmental Analysis; the specifics of quality assurance in environmental analysis have also been described elsewhere.\(^{85}\) In addition, USEPA Methods contain detailed (and mandatory) QC sections specific to the method of analysis. For instance, USEPA Methods 300.0 and 300.1 provide detailed instructions on QC procedures to be implemented when analyzing inorganic anions and DBP anions in environmental samples using IC.\(^{122,16}\) A sample of the requirements of a typical QC section contained in an IC method intended for environmental analysis is detailed in Table 8.\(^{86}\)

An ion-selective electrode (ISE) is an electroanalytical sensor that produces a potential whose magnitude is dictated by the activity of a small number of ions. The signal is generated by selective partitioning of a charged analyte across the sample–electrode interface. These sensors allow a wide range of environmental pollutants to be detected and quantified rapidly, sensitively and selectively. The ideal ISE can be inserted into the sample and will display the result of the chemical analysis within a few seconds with high precision and selectivity. Often no sampling, dilution or reagent addition is required, and changes in the analyte concentration or activity can be displayed in real time. Beyond the classical glass pH electrode invented in the early 1900s, the field now includes electrodes with several selective membranes for both sensing analytes and eliminating interferences, as well as ion-selective field-effect transistors (ISFETs). These new sensing approaches have greatly extended the range of environmentally relevant molecules that can be measured, and sensors exist for environmental pollutants as diverse as atmospheric carbon dioxide and radionucleotides in highly acidic solutions.

1 INTRODUCTION, OPPORTUNITIES AND ADVANTAGES

The technological development of the past century has seen a dramatic rise in emissions of anthropogenic pollutants. As a result, environmental analysis has become an area of intense interest for scientists and the public alike. The field has evolved, with the growing concern for the welfare of the environment requiring that qualitative and quantitative information on the nature, concentration and temporal changes in pollutants be available. Environmental monitoring is often mandated by legislation that places limits on allowable pollutant levels in soil, air and water samples. Furthermore, the financial penalties of “polluter pays” legislation make it essential for industrialists to continuously monitor their environmental impact. The challenge for analytical scientists is to provide suitable sensors for analysis of environmental samples in a sensitive, reproducible, rapid and accurate manner. This information is then applied to risk analysis, environmental impact studies and as a guide for remedial action. As shown in Table 1, these demands have led to the development of many important analytical approaches. Sensors have a significant role to play since they can be used, often on-site, to rapidly identify the type and concentration of pollutants. The goal of the analysis can range from preliminary, qualitative, field-screening to exposure assessments, time-dependent studies, speciation, etc. that require quantitative, dynamic information across a wide range of concentrations. Organic, inorganic and biological materials must be catered for and the impact of a wide range of sample matrices and interferences on the performance of the

Method assessed. Many of the pollutants detailed in Table 1 cause concern even when their concentrations are at the micromolar level. Thus, environmental analysis is often characterized by the need to measure trace levels, while demanding that the analytical technique has a high degree of selectivity, sensitivity, precision and accuracy.

Potentiometry fulfills these requirements for several species that pollute water, soil and air samples. The technique is distinguished by its versatility and simplicity, and the following list highlights some of the main advantages.

- **Portability**: the sensors and instrumentation are physically small, simple, and are often sufficiently robust to allow on-site monitoring of pollutants.
- **Sensitivity and dynamic range**: the logarithmic response of ISEs gives rise to a broad dynamic range in comparison with other analytical techniques such as spectroscopy. One reason why ISEs are especially attractive for environmental monitoring is that analytes can be determined over a wide range of concentrations using the same equipment with minimum changes in the analytical method.
- **Established technology**: the ISE is possibly the earliest example of a chemical sensor; preliminary reports of the pH electrode were made in 1906 by Cremer and subsequently in 1909 by Haber and Klemensiewicz who carried out systematic studies of the glass electrode’s response.\(^2\) Commercial production of the pH electrode commenced in the 1930s when Corning produced their NaO–CaO–SiO\textsubscript{2} glass electrodes. Research over the following decades improved the glass composition for pH analysis and also led to the production of other ion-selective glass electrodes. Other membrane systems have been developed in addition to glass, and ISEs are now firmly established as the most common chemical sensors.
- **Low reagent demand**: small volumes of solvents or reagents are required to perform an analysis.
- **Ease of use**: non-specialists can be quickly trained to operate and diagnose the performance of the sensors and instrumentation. Moreover, the data can be easily processed to extract quantitative information.
- **Multianalyte capabilities**: multiple sensors can be incorporated within a single device, either to improve the reliability of the analytical information or to allow the concentration of several target analytes to be measured within a single sample.
- **Continuous measurement**: with careful design, ISEs and ISFETs can be fabricated to provide meaningful information on the second and millisecond timescales. Therefore, while their use as detectors in chromatography is not especially widespread, they can be used in flow injection analysis (FIA) to achieve high sample-throughput and automated screening of samples.

2 PRINCIPLES

2.1 Background

An ISE is a potentiometric sensor that responds to the activity of certain ions. Figure 1 shows a general scheme for the measurement process. In ISEs, a selective membrane separates the internal reference solution and the analyte. Irrespective of whether the membrane is glass, a poly(vinyl chloride) (PVC) film containing an ionophore or a single lanthanum fluoride crystal, its function is to selectively exchange ions at the solution–membrane boundary. Ion exchange results in the formation of a potential difference which is measured using a high-input impedance voltmeter. The high-input impedance means that the voltmeter draws essentially no current through the electrochemical cell and the cell potential is measured under conditions that are very close to equilibrium.

2.2 Theoretical Considerations

For an ideal ion-specific membrane, the magnitude of the potential developed is related to the activity of a single ion in solution and is given by the Nernst equation (Equation 1)

\[
E = E_{\text{constant}} \pm \frac{RT}{zF} \ln[a_i]
\]

(Equation 1)
where $E_{\text{constant}}$ is the cell constant, $a_i$ is the activity of the ion in solution $i$, and $z$ is the charge on the ion. For an ideal membrane, the slope would be $59.16 \text{ mV} \text{ dec}^{-1}$ for a univalent cation at $25 \degree \text{ C}$.

In reality, all electrodes are selective rather than specific and ions other than the primary ion contribute to the observed potential. These ions represent interference to the measurement. Equation (2) describes the Nickolskii–Eisenmann equation that accounts for these interferences to the ISE response,

$$E = E_{\text{constant}} \pm \frac{RT}{z_j F} \ln a_k + \sum K_{ij}^{\text{pot}} a_l^{(z_k/z_j)}$$

where $a_k$ is the activity of the primary ion in solution $i$, $a_l$ is the activity of any interfering ion $l$, $z_k$ and $z_j$ are the charges on the primary and interfering ions, respectively, and $K_{ij}^{\text{pot}}$ is the selectivity coefficient of the electrode $j$ against the interfering ion $l$. The empirical selectivity coefficient is unique to a particular cell and measurement conditions. The summation term of Equation (2) indicates how well the ISE can discriminate between the primary ion and interferences. The smaller the value of $K_{ij}^{\text{pot}}$ the more selective the membrane. An ideal membrane would have $K_{ij}^{\text{pot}} = 0$ for all nonprimary ions and the Nickolskii–Eisenmann equation (Equation 2) would reduce to the Nernst equation (Equation 1). Typically a log scale is used to express the selectivity coefficients since ions that are dissimilar to the primary ion (principally through size and charge differences) will have selectivity coefficients close to zero, while similar ions may have $K_{ij}^{\text{pot}}$ close to unity. As illustrated in Figure 2, the concentration of interfering ions has a significant effect on both the linear calibration range and the limit of determination. Effects of this kind are especially important in environmental analysis, not only because low detection limits (DLs) are often essential, but because the absolute concentrations of interferences may be high. To reduce the influence of interferences, one seeks to use ISEs that exhibit the smallest values of the selectivity coefficient and hence $K_{ij}^{\text{pot}} a_i$. For many environmental samples, the background composition does not vary greatly from sample to sample. Thus, it is possible to use Equation (3) to estimate the maximum allowable value of the selectivity coefficient if the interferences are not to introduce error in the measured value of the primary ion activity, $a_i$, larger than $P_i$ percent.

$$K_{ij}^{\text{pot}} (\text{max}) = \frac{a_i(\text{min})}{a_i(\text{max})} \left( \frac{P_i}{100} \right)$$

where $a_i(\text{min})$ is the lowest expected activity of the primary ion and $a_i(\text{max})$ is the highest expected activity of the interferent. It may be possible to correct the responses of ISEs that fail to achieve the desired accuracy using numerical procedures.

2.3 Dynamic Range

The dynamic or response range of an ISE defines the range of concentrations of the analyte ion to which the electrode will provide an analytically meaningful signal. Instrumental noise is intrinsic to any technique and often defines the lower limit of detection (LOD). This LOD may be described as the lowest concentration level of analyte that can be determined to be statistically different from the associated analyte blank. In practice, the LOD is the concentration of analyte which provides...
a signal that is three times the standard deviation of the background noise. Typical ISEs for environmentally important analytes can be calibrated between approximately $10^{-2}$ and $10^{-1}$ M. The dilute end of this scale falls within the trace analysis range since $10^{-5}$ M corresponds to sub-parts per million (milligrams per kilogram) levels for simple anions and cations. It is sometimes possible to achieve even lower DLs by serial dilution of standards. However, use of ion buffers is an approach that can dramatically extend the calibration ranges of ISEs. However, use of ion buffers is an approach that can dramatically extend the calibration ranges of ISEs. Bakker has made significant contributions to improve the selectivity and sensitivity of ion-selective potentiometric and optical sensors. In particular, Mathison and Bakker recently reported on the effect of transmembrane electrolyte diffusion on the DL of carrier-based potentiometric ISEs. This work emphasizes the importance of considering the effects of both extraction and diffusion processes, e.g. the presence of lipophilic anions in the inner electrolyte solution increases the LOD owing to increased extraction into the membrane. Stirring the sample decreases the DL because it increases the mass transport rate from the membrane surface to the bulk sample. Bakker et al. highlighted the fact that many ionophores which achieve only micromolar LODs in ISEs can realize picomolar LODs in optically based approaches. In membrane-based ISEs, poor DLs may arise because of primary ions leaching from the internal filling solution into the sample. Sokalski et al. used an internal electrolyte with a low activity of the primary ion and a high activity of an interfering ion. This filling solution establishes a concentration gradient in the membrane causing a constant flux of the primary ion toward the inner compartment. In this way, the passage of the primary ion into the sample is prevented. Using this innovative approach, Sokalski et al. were able to push the conventional LOD for a Pb$^{2+}$ electrode from $4 \times 10^{-6}$ M to $5 \times 10^{-12}$ M!

3 PRACTICAL CONSIDERATIONS IN USING ION-SELECTIVE ELECTRODES FOR ENVIRONMENTAL ANALYSIS

3.1 Theoretical Versus Practical Analytical Conditions

While the conditions under which Equation (1) is obeyed are well defined, they are not necessarily fulfilled for practical analysis, which may cause measurement errors. For example, the Nernst equation is based on thermodynamic principles and is strictly applicable only to ideally reversible systems. However, potentiometric measurements are usually carried out at relatively short timescales, typically tens of seconds, and the Nernst (Nickolskii–Eisenmann) equation may be incorrectly applied to systems that are electrochemically irreversible over long periods. Moreover, besides the desirable ion-exchange reaction of the primary ion, there are several other processes that can contribute to the observed potential change, including redox, adsorption and membrane dissolution processes. The Nernst equation is not strictly applicable under these circumstances since it is valid only when one well-defined process occurs at an electrode. These secondary processes limit the range over which there is a linear dependence between potential and log activity.

3.2 Activity Versus Concentration

As discussed, the Nernst equation underpins the operation of ISEs. Therefore, it is the activity of ions in solutions that is actually measured. Measuring activity rather than concentration is advantageous for speciation purposes and for the study of acid–base, complexation and precipitation equilibria. However, it represents a significant disadvantage when the objective is to measure the total content, i.e. both free and bound forms, of an analyte in a sample. As discussed later, where the total content is important, the analyte must be released from the matrix by chemical pretreatment or distillation.

Determining the true activity of an ion in solution places considerable demands on the analytical procedures employed and the manner in which the samples are handled. In particular, the following conditions must be met.

(1) Chemical pretreatments, e.g. reagent addition, evaporation, dilution or freeze-drying must be avoided.

(2) The relationship between the signal and the ion activity must be known, i.e. the response function of the ISE under identical operating conditions must be determined so as to calibrate the response.

(3) The ISE should be specific, i.e. broad-band selectivity is not adequate, since the Nernst equation applies only to electrochemical systems involving a single well-defined process. The sample cannot be chemically modified to mask interferences.

Therefore, in the context of environmental monitoring, samples should ideally be analyzed in situ or directly read at a later stage without the addition of further reagents. This condition is often difficult or impossible to achieve because analytes that are of environmental interest must be preconcentrated, treated or digested prior to analysis because of low concentrations or matrix effects.
3.3 Calibration

The selectivity coefficient should equal the thermodynamic exchange constant for the transfer of an ion from solution into the selective membrane of the ISE under equilibrium conditions. Therefore, $K^\text{ps}$ is sensitive to both the selective element within the membrane, e.g. the host within a host–guest complex, and to the composition of the membrane. For example, for polymer-membrane-based ISEs, the solvent, plasticizer, polymer, and their respective concentrations, will all influence the transmembrane transport processes and hence the selectivity coefficients. Thus, there are several possible difficulties in both the calibration of individual sensors and comparing calibration data between separate devices.

First, changing ionic strength or variable liquid junction potentials may mean that the standard cell potential $E^\circ$ is not constant over the entire concentration range. This shift will cause nonlinear calibrations or non-Nernstian slopes to be observed. Moreover, an incorrect membrane composition or redox-active impurities may mean that the characteristic electrode slope is not given by $RT/zF$. Processes such as slow partitioning of the analyte across the membrane/solution boundary, slow diffusion within the membrane or adsorption/desorption cause many ISEs to be slow to reach equilibrium. Failure to achieve global equilibrium means that the apparent selectivity coefficients become time dependent. This “kinetic selectivity” has been exploited in high-throughput FIA to improve the overall analytical performance, since the short timescale response is often more sensitive to the primary ion concentration than to interferences.

Second, the composition of the membrane may change significantly over time. For example, leaching of the ionophore can be a particular problem for liquid-state electrodes where the ionophores and plasticizer are typically only physically entrapped within the matrix and tend to dissolve into the samples. Also, partitioning of water and lipophilic sample components into the ISE element will decrease the ionophore concentration within the membrane. The most significant effect of reducing the ionophore loading is to decrease the sensor’s sensitivity, but to degrade its ability to discriminate between ions. In the most extreme situation, the sensor loses the selectivity achieved by the incorporated ionophore and the sensor response will ultimately follow the Hofmeister or lyotropic series, e.g. for anions $SO_4^{2-} > CF_3COO^- > Br^- > ClO_4^- \approx NO_3^-$, and for cations $Na^+ > Ca^{2+} \approx K^+ > NH_4^+ > Li^+$. 

Third, the electrode geometry and measuring conditions must be considered. For example, macroscopic and microscopic ISEs constructed using identical materials and techniques can exhibit differences in the observed potential of 10 mV or more. These differences may arise because the membrane properties depend on the electrode’s size. However, there is some evidence that, as found for amperometric microsensors, changes in the mass transport mode with size may influence the rate of ion exchange at the membrane/solution interface. These effects may give rise to an electrokinetic potential causing the electrode slope observed at a microelectrode to decrease relative to that observed for a macroelectrode.

Fourth, the background composition of the solutions must be constant if measurements or devices are to be compared. Here, our focus is on the possibility that the composition of the solution at the membrane/solution interface differs from that of bulk. These differences may arise simply because of the ion-exchange reaction itself or because solvent or other components partition into, or out of, the sensing element.

3.4 Reference Electrodes

As illustrated in Figure 1, a reference electrode is an integral part of ISE measurements since it is against this potential that the ISE signal is measured. If operated incorrectly, then the reference electrode can act as a source of significant error. Temperature is an important variable in many environmental monitoring situations, especially for in situ water quality monitoring since the temperature can change dramatically with depth. However, the reference electrode potential is temperature dependent, e.g. for the traditional calomel reference electrode the reference potential shifts by approximately 0.7 mV K$^{-1}$. In real terms, this shift translates into a few percent relative error on measurements performed a few degrees apart. Also, as described by the Nernst equation (Equation 1), the ISE potential depends on the temperature. Therefore, it is important that the analysis and calibration temperatures are closely matched if accurate results are to be obtained. An alternative is to use a reference electrode, such as the Zn/ZnCl$_2$ system, whose potential is very insensitive to temperature.

It is also highly desirable to make the electrochemical cell as symmetrical as possible to minimize the effect of changes in temperature on the observed potential. This objective means not only that the same internal and external reference electrodes are used, but that the composition of the inner filling solution of the ISE matches the sample composition as closely as possible. Thus, in contrast to most reference electrode filling solutions where 6M or even saturated solutions are commonly used, ISEs are often filled with a 0.1 M solution of the primary ion. This lower concentration within the internal filling solution also helps prevent contamination of the samples by leakage, e.g. in the case of chloride determination.
3.5 Response Time
Under special conditions, ISEs can respond rapidly to abrupt changes in the concentration of their primary ion around the midpoint of their calibration range, achieving 90% of the total potential change within 100 ms. However, typical ISEs respond much more slowly with equilibrium responses only being obtained after seconds or even tens of seconds.

3.6 Quality Control in Ion-selective Electrode Measurements
Quality control is an important issue when using ISEs for environmental analysis, to ensure accurate and reproducible results. A typical quality control system involves periodic confirmation of the ISE calibration by determining the concentration of a known, independently prepared sample. For example, immediately after an ISE is calibrated, an initial calibration verification (ICV) standard should be analyzed. The ICV contains a known concentration of the primary ion close to the midpoint of the calibration range and is prepared independently of the calibration standards. For acceptable performance, the ICV recovery must be between 90% and 110% otherwise the source of error must be identified and corrected. This verification standard is typically analyzed after every ten samples. If the ISE calibration has changed, all samples analyzed since the last acceptable continuing calibration verification (CCV) standard, must be re-analyzed. After each ICV and CCV sample analyzed, a reagent blank is often analyzed. This blank is frequently high-purity water but, if reagents are being added to the samples, then a 1:1 dilution of the buffer is often used. The objective in measuring the blank is to identify possible contamination of the samples. Spiking the samples is another common approach to ensure that quality measurements are performed. The spike concentration must be ten times the DL and the volume added must be negligible (less than or equal to one-thousandth of the sample volume). Spike recovery must be 75–125%, otherwise samples must be analyzed by performing standard additions.

4 TYPES OF ION-SELECTIVE ELECTRODES
All ISEs rely on a membrane to separate the analyte and reference solutions. Therefore, ISEs may be conveniently classified according to the nature of this membrane material. While the membranes may absorb solvent, ideally they are as immiscible as possible with their analyte solution. Hydrophobic organic liquid ion-exchange electrolytes, solid polyelectrolyte ion exchangers and solid ion-conducting electrolytes are the most frequently employed electrode membranes types. The best membranes are ionically conducting, for example solid or liquid electrolytes that contain substances which ionize depending on the membrane dielectric constant and extent of solvent penetration.

4.1 Solid-membrane Electrodes
The success of the pH glass electrode is without parallel in sensors. Although somewhat mechanically fragile, it resists a wide variety of sample media and, with the exception of hydroxide, is largely free from interferences. Moreover, pH-sensitive glass electrodes form the basis of many successful sensors for environmentally important gases including carbon dioxide, sulfur dioxide and nitric oxide. Thus, glass membranes represent an important class of solid-membrane ISEs. As illustrated in Figure 3, these ISEs have a thin glass membrane fused to the end of a glass or plastic body. The main body of the electrode contains an internal reference electrode, typically Ag/AgCl, and is filled with a solution that is usually the chloride salt of the primary ion. The membranes are primarily made from lithia, aluminosilicate or multicomponent glasses whose selectivity pattern depends on the composition of the glass. As shown in Table 2, excellent discrimination against common cationic species is achieved. There are no anion-selective glass membrane materials and glass membranes are primarily used for sensing of monovalent cations.

As illustrated in Figure 4, homogeneous membrane electrodes contain insoluble crystalline materials either

![Figure 3](image-url) Schematic diagram of a typical glass electrode. The internal reference electrode is usually Ag/AgCl.

mechanical robustness of the sensor. However, plastics may include sensors for pollutants such as cadmium, cyanide and lead.

In contrast, heterogeneous membrane electrodes comprise an active crystalline material dispersed through another matrix, for example a polymer that improves the durability of an electrode material, and, as shown in Table 3, many useful sensors have been developed using these approaches.

### 4.2 Liquid Ion-exchange Electrode

As illustrated in Figure 5, the traditional membrane of a liquid ion-exchange electrode consists of a homogeneous, organic, water-immiscible liquid absorbed into a millipore or nucleopore filter that incorporates mobile, ionic components. The mobile ionophores include compounds such as hydrophobic acids, bases or salts. Liquid membranes typically show Nernstian responses in the absence of interferences, usually for oppositely charged counterions to their own electrical charge. This design is more flexible than the solid-membrane materials considered in section 4.1 and ISEs sensitive to a much wider range of compounds can be fabricated using this arrangement, including $K^+$, $Ca^{2+}$ and the environmentally important $NO_3^-$ ions. However, these ISEs have been largely superseded by other approaches, notably neutral carrier sensors, because of technical problems.

These difficulties include imperfect filling of the support membrane pores by the ionophoric liquid, leading to sample permeation into the internal filling solution that “short circuits” and fails to generate a measurable transmembrane potential. Also, the liquid membranes themselves tend to be somewhat unstable, becoming contaminated by lipophilic substances within the samples or mechanically dislodged from the support if mishandled.

Neutral-carrier ISEs are typically based on PVC in which a suitable electrically neutral ionophore, plasticizer and ion-exchanger are co-immobilized. The ionophores typically possess a polar cavity that contains electron-donating atoms or polar groups capable of interacting with the target ions. The stability of the complex, and hence the selectivity coefficient, is determined by a “best-fit” mechanism and the neutral carrier is more selective towards ions that best fit the molecular cavity. Larger ions will not be able to effectively penetrate the cavity, while smaller ions will interact with too few donor atoms to form stable complexes. The strength of binding must be carefully balanced, since while strong binding favors specificity, forming too strong a complex will lead to irreversible responses. The types of molecules used in neutral-carrier ISEs continues to expand, and include crown ethers, calixarenes, complex macromolecules, and antibiotics such as valinomycin and nonactin. Neutral-carrier ISEs are commonly used for ions such as Na⁺, K⁺, Li⁺, NH₄⁺, Ca²⁺, Cs⁺ and Ba²⁺.

4.3 Gas-sensing Membrane Electrodes

Gas sensing is an extremely important aspect of environmental monitoring in areas ranging from smokestack emissions, notably for sulfur and nitrogen oxides, to carbon dioxide levels in ambient air. The earliest and most commercially successful gas-sensing probe is based on the Severinghaus electrode, in which a glass pH-electrode is placed behind a gas-permeable membrane. Table 4 shows common gas-sensing electrodes that are important in environmental analysis. These electrodes differ from those described above in two important ways. First, they do not directly detect the target analyte. They are not true ISEs, but are complete electrochemical cells capable of indirectly determining the concentration of the target analytes using a conventional ISE that is internal to the cell. A popular approach to gas sensing is to analyze the by-products of the target chemical’s reaction with the internal electrolyte, most commonly by monitoring pH changes in the cell. Second, because of the mode of operation, gas-sensing electrodes employ two membranes; the first allows the gas of interest to permeate into the electrochemical cell, and the second selectively generates the ISE potential.

Figure 6 shows a schematic of a typical gas-sensing probe. The probe comprises an outer gas-permeable membrane which prevents nongaseous interferences from accessing the inner cell. Once dissolved in the inner-cell filling solution, the analyte establishes a chemical equilibrium with the electrolyte and the products are then detected by the internal ISE. Gas-sensing probes are often highly selective since many interferences are removed by the gas-permeable outer membrane and the analyzing ISE is typically a highly selective pH electrode. The main disadvantages of such sensors are their poor long-term stability and their long response times, associated with the slow rate of gas diffusion across the membrane.

The second type of gas-sensing ISE is the air-gap electrode. In this arrangement, the internal filling solution surrounds the internal ISE’s surface as a thin film, and an air bubble replaces the outer gas-permeable membrane.

This arrangement offers some advantages over the Severinghaus-type electrode in terms of sensitivity and response time. However, the electrode surface must not be allowed to dip into the analyte solution. The electrode is operated by passing the analyte close to the electrode surface, either in the form of a gas stream or, for solution samples, by stirring the sample solution rapidly in the presence of the electrode. The air-gap cyanide sensor is an example of such an arrangement and has important applications in atmospheric analysis.

4.4 Solid-contact and Coated-wire Ion-selective Electrodes

Solid-state electrodes of the types illustrated in Figures 7 and 8 that do not contain free-flowing liquids represent an important and growing area of ISE research. Unlike conventional solution filled sensors, their response does not depend on orientation, they can be more easily miniaturized and they are mechanically flexible. As illustrated in Figure 8, coated-wire electrodes (CWEs) are formed by depositing a thin layer of material, often a polymer, onto the surface of an inert metal wire such as platinum or gold. CWEs have the advantages of rapid response, small size and suitability for temperature and noise compensation and for the manufacture of arrays. The difficulty with these sensors is that the potential that develops at the layer/wire interface can be unstable over long periods.

4.5 Arrays

Using a single sensor to determine the concentration of an analyte demands that it be extremely selective if its response is to be overwhelmingly dominated by a single ion. Combining several individual sensors within an array is attractive since it allows multicomponent analyses to be performed and provides the high-quality analytical information necessary to model the role of interferences. Accurate modeling of the array response may allow partially selective sensors to be used. Moreover redundancy, i.e. having more than one sensor within the array that is capable of performing the analysis, leads to more reliable sensing systems. Beyond these issues, considerable attention is being paid to developing “smart” sensors with much improved abilities to process analytical information. A smart sensor exhibits the following characteristics:

- able to process information for automatic calibration or compensation of baseline drift
- can communicate with other sensors or devices
- adapts to changes in its environment, e.g. automatic temperature compensation
With the exception of true liquid-membrane electrodes, all of the ISEs described can formally be integrated within a sensor array. However, those that employ fabrication procedures that can produce planar membranes, e.g., solid-state and neutral-carrier membranes, are the most amenable to producing arrays. Another important consideration in selecting ISEs for arrays is the stability of the calibration. Stability, rather than selectivity, is perhaps the single most important issue in sensor arrays. For example, a factorial design is preferred for calibration purposes requiring $L^{f-1}$ solutions, where $L$ is the number of levels (e.g., high and low concentrations) and $f$ is the number of factors (e.g., four ions). Thus, to calibrate a four-electrode array using a two-level, four-factor design requires 32 solutions. Clearly, the sensor output must be stable during this calibration and subsequent measuring period if an accurate model is to be constructed. Highly selective sensors are not necessarily desirable since an artificially high concentration of the interferences must be used to sufficiently perturb the sensor response.

### 4.6 Ion-selective Field-effect Transistors

ISFETs\(^{(24–26)}\) represent a hybrid of technologies from solid-state physics and electrochemistry. As shown in Figure 9, ISFETs employ conventional ion-selective membranes that either replace the gate of a metal-oxide field-effect transistor (MOSFET) or are placed in direct contact with the gate. The intense interest in these devices during the late 1970s and 1980s has decreased somewhat recently because of the problems in establishing a stable internal reference potential where the PVC membrane comes in contact with the field-effect transistor (FET) surface. Also, solid-state sensors tend to suffer from poor sensor-to-sensor reproducibility even within a single batch of devices, requiring that sensors be calibrated individually. However, better fabrication technologies, materials and visualization techniques promise to solve many of these problems.

![Figure 9 Typical ISFET.](image)

The main advantages of ISFETs are their small size; the fact that they are compatible with planar silicon-processing technology, allowing them to be cheaply mass-produced; the ease with which they can be incorporated into arrays; the rapidity with which they respond to changes in analyte concentration; and their low impedance which makes them much less sensitive to electromagnetic interference. Depending on the materials used in their construction, light exposure may need to be controlled to obtain accurate readings.

Similar to a metal-oxide semiconductor FET, in an ISFET electric current flows from the source to the drain via a channel. The channel resistance depends on the electric field perpendicular to the direction of the current and on the potential difference over the gate oxide. Therefore, the source–drain current, $i_{ds}$, is influenced by the potential at the oxide/aqueous solution interface. At a fixed source–drain potential ($V_{gs}$), changes in the gate potential can be compensated by modulation of the gate–source potential, $V_{gs}$. This adjustment should be carried out in such a way that the changes in $V_{gs}$ applied to the reference electrode are exactly opposite to the changes in the gate-oxide potential. This is automatically performed by the ISFET feedback amplifier that allows one to obtain constant source–drain current. In this case, the gate–source potential is determined by the surface potential at the insulator/electrolyte interface.

When SiO$_2$ is used as the insulator, the chemical nature of the interface oxide is reflected in the measured source–drain current. The surface of the gate oxide contains OH$^-$ functionalities, which will be in electrochemical equilibrium with ions in the sample solutions (H$_3$O$^+$ and OH$^-$). The hydroxyl groups at the gate-oxide surface can be protonated and deprotonated and thus, when the gate oxide contacts an aqueous solution, a change of pH will change the SiO$_2$ surface potential. Typical pH sensitivities measured with SiO$_2$ ISFETs are $37–40$ mV per pH unit rather than the 59 mV per pH unit predicted by the Nernst equation\(^{(27)}\). However, significant improvements on this performance have recently been achieved by using pH-ISFETs based on silicon nitride and tantalum oxide gates. In the Si$_3$N$_4$ system, silanol and amine sites make the assembly sensitive to the solution pH, while in the Ta$_2$O$_5$ ISFETs, Ta–O sites provide the pH sensitivity and close to ideal Nernstian behavior is observed\(^{(28)}\).

The selectivity and chemical sensitivity of the ISFET are completely controlled by the properties of the electrolyte/insulator interface. Therefore, by immobilizing a suitable membrane on the gate oxide, solid-state sensors for a range of environmentally important analytes can be fabricated.
5 ION-SELECTIVE ELECTRODES IN ENVIRONMENTAL ANALYSIS

The application of ISEs to environmental analysis can be divided into two different approaches. First, solution-phase analysis, e.g. water and effluent analysis. Second, gas-phase analysis, e.g. smokestack emissions and airborne pollutants. Many environmental monitoring applications require dynamic information about changing sample compositions within relatively short periods of time. One useful approach to achieving a high sample-throughput is FIA and we first review its mode of operation.

5.1 Techniques: Flow Injection Analysis

Although their responses are often too slow for use as end-column detectors in chromatography, the selectivity of ISEs can be exploited to achieve a high sample-throughput using FIA. Continuous methods in environmental analysis offer significant advantages over more traditional batch methods. Most importantly, it provides a means of observing temporal changes in environmentally important agents and may offer advance warning of impending pollution.

As described in the seminal work of Ruzicka,\(^29\) in the flow injection method a carrier stream is continuously pumped around an analytical manifold and reproducible volumes of sample are injected into the stream at selected intervals.\(^30\) After passage through reaction structures in the analytical assembly, the product or unreacted sample is passed to the detector, producing a signal whose magnitude depends directly on the concentration of the analyte. Usually the carrier contains a low concentration of the analyte ion in order to stabilize the ISE membrane potential. As illustrated in Figure 10, since the sample plug contains a higher concentration of the analyte, the analytical signal is an unsymmetrical peak whose shape reflects the effects of hydrodynamics and the kinetics of ion uptake and release.

As illustrated in Figure 11, the ISE can be integrated into the analytical assembly in one of four ways, namely by a flow-through, flow-past, tangential or wall-jet regime. In the flow-through and flow-past approaches, the electrode membrane replaces part of the tubing through which the analyte stream is travelling. In the tangential approach, the sample and membrane are at an acute angle of less than 90°, while in the wall-jet method the sample stream approaches the membrane at 90° and is then dispersed at the sides.

Operating ISEs in flowing streams offers a number of advantages over a batch-type approach. The Nernst diffusion layer that exists close to the membrane/solution interface is highly reproducible and stable, giving improved response times and very reproducible signals. Contamination problems arising from leaking reference electrodes are eliminated since the reference can be placed downstream of the detection point. The carrier solution can be easily modified so as to optimize the selective response of the ISE, e.g. controlling the ionic strength, masking interferences, etc. FIA offers a high sample-throughput, e.g. the flow rate is typically 0.5–1.0 ml min\(^{-1}\) and a 100 µl sample stays in contact with the membrane for only 6 s. Provided that the return to baseline is rapid, throughputs of 120 samples per hour or even higher may be achieved. Table 5 contains some examples where ISEs coupled to FIA have been exploited in environmental analysis.

FIA/ISE systems have been developed for use without a requirement for a preceding separation step. For example, copper has been determined in tap water

![Figure 10](#) Typical FIA/ISE peak. The injection is made when the membrane is in equilibrium with the carrier solution. During the period labeled (a), the ISE potential increases rapidly owing to the boundary potential. A pseudo-steady-state situation is reached at the top of the peak (b). As the plug leaves the detector (c) and the membrane-carrier equilibrium is re-established, the potential returns to the baseline.

![Figure 11](#) Different flow regimes used in FIA/ISE systems: (a) flow-through, (b) flow-past, (c) tangential and (d) wall-jet assemblies.

using a detection system comprising two Cu²⁺ selective electrodes as indicator and reference. In common with most FIA/ISE analyses, a relatively high concentration of electrolyte (0.1 M KNO₃ in this case) was added to the carrier stream to ensure a steady baseline. The results obtained compare well with those observed using a standard spectrophotometric approach. Moreover, as highlighted in Table 5, the primary ion is frequently added to the carrier stream, e.g. 5000 ppm cyanide was added to the carrier stream during the determination of cyanide in wastewater. Interferences from trace metal can be removed on-line using chelating ion-exchangers. This approach achieves DLs that are between 10⁻⁷ and 10⁻⁸ M.

Flow injection also lends itself to multianalyte determinations by incorporating as many ISEs as there are analytes into the detection manifold. The sensors are often placed in series. However, careful attention must be paid to achieving minimum dispersion and dead volume, i.e. high fluid velocities and well-defined sample plugs across each sensor should be employed. Multi-ion analyzers have been constructed to monitor potassium, calcium, nitrate and chloride in soil extracts, and to determine sodium, potassium, calcium, bicarbonate, nitrate and chloride in drinking water.

While FIA certainly has the great advantages of high sample-throughput and highly reproducible sample handling, there are some difficulties in using ISEs as
detectors in FIA. First, as discussed in section 2.2 dealing with theoretical issues, the analyte often does not reach global equilibrium with the sensing element even for slow flow rates or stopped flow approaches. Since kinetic selectivity often depends on the analyte concentration it causes plots of potential vs logarithm of analyte activity to become nonlinear. Therefore, slow transport or other kinetic difficulties can be a source of calibration errors because the rate at which equilibrium is achieved differs between standards and samples. Second, when the dilute electrolyte carrier solution moves along the ISE surface, excess charges outside the double layer are carried along by the flow, causing a streaming potential. The magnitude of the streaming potential depends on the ionic strength of the carrier, the solvent viscosity and the flow rate. It can be reduced by either stopping the flow to make the measurement or by using a carrier of high ionic strength. Another important technical consideration is contamination of the electrodes by components within the samples, e.g. highly lipophilic species in the case of neutral carrier ISEs. However, the short residence time of the sample compared with batch-type measurements usually means that this is a minor problem.

5.2 Water-based Monitoring

The late twentieth century has seen a dramatic increase in the consumption of water for domestic, agricultural and industrial purposes. As water is recycled, it is important to confirm that the water quality is acceptable and that it will not contaminate other stocks, e.g. reservoirs, storage tanks, rivers, lakes, etc. Historically, water analysis often involved simply checking the pH and biological oxygen demand, with the total salt concentration being estimated from the solution conductivity. However, this nonspecific information is becoming increasingly inadequate as limits are set for acceptable discharge levels for a wide variety of analytes ranging from heavy metals to anions. Potentiometry plays an important role in providing direct information about the concentrations of many important pollutants in potable and naturally occurring bodies of water.

5.2.1 Metallic Species

The ability to determine in situ the distribution of metal species using a simple, rapid technique is extremely valuable since the toxicity, transport and ultimate fate of the metallic species depends not only on the identity of the species in question but also on their oxidation state. Current environmental protection methods, e.g. those that have been evaluated and approved for use by the United States Environmental Protection Agency (USEPA), focus heavily on the use of AAS for the determination of metals in the environment. However, AAS destroys the sample, requires a separate protocol for each metal, cannot differentiate valence states or species, is expensive and time-consuming and has difficulty in simultaneously determining the concentration of several metals. Therefore, there is growing interest in using ISEs for the environmental monitoring of metallic species.

5.2.1.1 Mercury

Classical mercury ISEs exhibit linear calibration ranges in the $10^{-5} - 10^{-7}$ M range. However, the unbound Hg$^{2+}$ concentration is often in the $10^{-9}$ M range in natural environments. Therefore, highly sensitive sensors that are almost completely mercury specific, or whose responses can be corrected for the effects of interferences, are required. Epoxy-based ISEs have been developed that are capable of determining Hg$^{2+}$ concentrations at the $10^{-14}$ M level, making them useful tools for the determination of both free and inorganic-bound mercury in natural waters. However, Fe$^{3+}$ represents a significant interference, not only because of poor selectivity, but also because Fe$^{3+}$ can be present at high concentrations in environmental samples.

Host molecules capable of selectively binding heavy metals have been immobilized within PVC membranes to form polymeric ISEs. For example, calixarenes have been synthesized that incorporate soft donor atoms, such as nitrogen and sulfur, within the ion-binding cavity to create hosts for ISEs that are sensitive to Hg(II), Ag(I), Cu(II) and Pb(II). A combination of the correct number and location of soft donor atoms makes the calixarenes selective for heavy metals rather than the alkali cations that are usually the primary ions for calixarene-based ISEs.

5.2.1.2 Lead

The lead electrode is useful for monitoring aqueous concentrations of Pb$^{2+}$. Provided that the sample pH is between approximately 4 and 7, the linear range typically extends from $10^{-1}$ to $10^{-6}$ M with a DL of $10^{-7}$ M being observed. Under basic conditions, the LOD is restricted because of the formation of metal hydroxides. At lower pH values, the lead and silver sulfides used to form the sensing element become more soluble causing the LOD to increase. The ability of the ISE to discriminate against alkali and alkaline earth metals is good, but Cu$^{2+}$ and Fe$^{3+}$ represent significant interferences. High concentrations of chloride may also cause difficulties in accurately monitoring lead levels. In practical use, the surface of the electrode tends to become oxidized, and mechanical or electrochemical repolishing is required periodically. The lead electrode has also been quite widely used for the indirect determination of sulfate.

5.2.1.3 Copper

Copper-sensitive ISEs can be formed by co-precipitation of copper and silver sulfides that are then pressed and sintered to form disks. Alternatively, the precipitate can be dispersed within an inert binder.
The resulting sensing element contains an intimate mixture of the two sulfides and a ternary compound jalapite (Ag$_1$5Cu$_0$5S). Mercury (II), silver (I) and chloride interfere significantly in the copper determinations. In common with the lead and cadmium electrodes, the response of the copper ISE does not always give the predicted Nernst slope of approximately 30 mV dec$^{-1}$ when complexes are present. The DL for free metal concentrations is impressive, at $10^{-10}$ M, but is rarely required in environmental analysis where divalent metal ion concentrations are normally above $10^{-7}$ M.

5.2.2.2 Cyanide Cyanide in aqueous samples is an environmentally important analyte that can be quantified using a potentiometric sensor. Using this approach, the free cyanide and hydrocyanic acid concentration can be measured, or the total cyanide level determined if the sample is first distilled. The DL is 0.05 ppm and cyanide concentrations from 0.01 to 10 ppm can be determined. However, results less than 0.05 ppm may be up to 120% too high. The main interferences arise from transition metal ions that form strong complexes with cyanide which cannot be measured by the ISE. Distillation decomposes the metal–analyte complexes allowing the total cyanide concentration to be determined. The method can be extended to the analysis of soil samples after a suitable extraction step.

5.2.2 Anions

5.2.2.1 Chloride ISEs are approved by the USEPA for the determination of simple chloride ions in drinking waters, natural surface waters, groundwaters, domestic and industrial wastewaters and in soil extracts. The DL of the method is 2.0 ppm and chloride concentrations between 0.4 and 1000 ppm can be measured, although concentrations less than 2.0 ppm can be overestimated by approximately 60%. Measurements in solutions that contain high levels of iodide, cyanide or sulfide should be avoided since these anions form silver salts that are less soluble than silver chloride, which forms the basis of the sensor. Erroneous readings may also be obtained if the sensor is exposed to ammonia, because these solutions tend to dissolve silver chloride. Sulfide, cyanide and ammonia can be removed as interferences by acidiﬁcation of the solution to pH 4 using sulfuric acid, while addition of acidified potassium bromate oxidizes the iodide and bromide and removes them as interferences. Other interferences arise from metal ions, e.g. Fe$^{3+}$ and Al$^{3+}$, that complex chloride preventing it from being measured. Under these circumstances, the sample is usually treated with EDTA, which forms strong complexes with the metal ions.

5.2.2.2 Cyanide Cyanide in aqueous samples is an environmentally important analyte that can be quantified using a potentiometric sensor. Using this approach, the free cyanide and hydrocyanic acid concentration can be measured, or the total cyanide level determined if the sample is first distilled. The DL is 0.05 ppm and cyanide concentrations from 0.01 to 10 ppm can be determined. However, results less than 0.05 ppm may be up to 120% too high. The main interferences arise from transition metal ions that form strong complexes with cyanide which cannot be measured by the ISE. Distillation decomposes the metal–analyte complexes allowing the total cyanide concentration to be determined. The method can be extended to the analysis of soil samples after a suitable extraction step.

5.2.2.3 Fluoride The first significant anion-selective ISE was the fluoride-selective electrode reported by Frant and Ross in 1966. This sensor is especially important as there are not many alternative methods available for fluoride monitoring. The selectivity and overall performance of this sensor are impressive, with hydroxyl representing the only significant interference. The determination of fluoride levels in potable water is important since a level of 1 ppm fluoride is recommended to promote dental health. The fluoride ISE offers excellent performance, with a typical DL of 0.5 ppm and a linear range between 0.025 and 500 ppm being obtained. However, using a linear calibration procedure may result in samples with fluoride concentrations less than 0.5 ppm being read approximately 160% too high. As the objective is always to determine the total, rather than free, fluoride concentration, this problem can be reduced by adding a buffer to adjust the total ionic strength which contains a strong metal chelator. The sample pH is a critical issue since the selectivity coefficient for hydroxide is approximately 0.1. Therefore, the pH is usually adjusted to between 5 and 5.5. Too acidic a medium should be avoided because at low pH values fluoride forms HF$_2^-$ which cannot be detected by the ISE.

There is a long history of using ISEs for industrial hygiene monitoring, especially through the determination of fluoride in urine. A National Institute of Occupational Safety and Health (NIOSH) method for fluoride has been established using this analytical approach. In keeping with the demands of the workplace, the method is uncomplicated and involves the simple dilution of a urine sample with buffer, and direct measurement of the fluoride activity using the ISE. The addition of the pH buffer
5.2.2.4 Sulfide ISEs can be used to determine the total sulfide concentration in aqueous samples. The method is applicable only to samples distilled from a scrubber solution that contains oxygen scavengers such as salicylic or ascorbic acid, because of possible interference from mercury and silver. Also, distillation decomposes sulfide complexes to free sulfide dianions that can be determined by the ISE. The calibration range is between approximately 0.1 and 12 000 ppm. Results obtained for solutions containing less than 1 ppm sulfide may be approximately 90% too low. Silver, mercury, humic acid or thiosulfate do not interfere significantly with the analysis.

Underground corrosion, spoilage of petrol, paper pulp and foodstuffs can be caused by anaerobic sulfate-reducing bacteria. Therefore, the detection of these bacteria is an important economic objective. The sulfide ISE is not only capable of determining sulfide concentrations at the parts per billion level, it can also detect the initial growth of sulfate-reducing bacteria. Further studies demonstrated that sulfate, sulfite, thiosulfate, pyrosulfite and dithionite, but not dithionate, are converted stoichiometrically to sulfide by bacteria such as Desulfovibrio desulfuricans, D. gigas and D. vulgaris. Sulfide ISEs have also been used to monitor sulfide and thiols in petroleum process streams.

5.2.2.5 Nitrate The USEPA has deleted the brucine–sulfanilamide method for determining the solubilized nitrate concentration (method 9200) and replaced it by an ISE method. The original approach has been abandoned because it produced unreliable results. The ISE method gives a LOD of 2.0 ppm and nitrate concentrations from 0.2 to 1000 ppm can be measured. It is important to note that simple linear calibration models can introduce significant errors at both the high and low ends of this range. For example, results obtained for samples containing <2 ppm nitrate may be up to 400% too high, while results for solutions containing >400 ppm nitrate may underestimate the nitrate concentration by approximately 50%. The nitrate ISE is prone to a number of interferences that are typically masked by adding appropriate reagents. For example, cyanide, bisulfide, bicarbonate, carbonate and phosphate are removed as interferences by adjusting the pH to 4 with boric acid. The halides are removed as precipitates by adding silver sulfate. Nitrite can be removed by adding sulfamic acid. As discussed in section 3.2, adding reagents will change the ionic strength of the sample, which may in turn change the activity of the target ion thus altering the ISE potential. Therefore, one must be careful that samples and calibration standards are treated similarly, or that an ionic-strength-adjusting buffer is used. Also, some prior knowledge of the interference concentration is desirable if the interferences are to be successfully eliminated. One must also be careful about contaminating the samples with chloride, e.g. from a leaking saturated calomel reference electrode, and the use of a mercury sulfate reference is recommended.

While the nitrate-selective electrode discriminates well between nitrate and chloride, $K_{\text{pot}}^{\text{NO3/Cl}} = 4 \times 10^{-3}$, it is in fact more sensitive to perchlorate than nitrate, $K_{\text{pot}}^{\text{NO3/ClO4}} = 550$. Therefore, the nitrate ISE is prone to a strong interference from perchlorate. However, perchlorate is rarely present in samples where nitrate has to be determined. Despite the small value observed for $K_{\text{pot}}^{\text{NO3/Cl}}$, the response of the nitrate electrode will be compromised where the chloride concentration is high. This difficulty has lead to the use of “ion-buffers” for sample pretreatment. In the case of a high background chloride concentration, silver sulfate is added to form a precipitate. Other “buffers” include the addition of aluminum sulfate to complex anions of organic acids, and the use of boric and sulphamic acid to decompose nitrite. When using these pretreatments, it is necessary to adjust the pH to approximately 3 by adding sulfuric acid so that any organic acids present remain undissociated and the hydrogen carbonate level is controlled.

5.2.2.6 Nitrite Nitrite levels within aqueous environmental samples can also be determined using an ISE. The DL of the method is 0.05 ppm with a calibration range that extends from 0.05 to 20 ppm. In common with many anion determinations by ISE, when measuring nitrite levels a buffer that adjusts the sample pH and masks interferences must be added. Table 6 summarizes the selectivity coefficients observed for major interferences of the method.

5.2.3 Miscellaneous Species

5.2.3.1 Ammonia The gas-sensing ammonia electrode, the ammonium-sensitive liquid-membrane electrode and the ammonium-sensitive glass electrode can be used for determining ammonia in water. The liquid-membrane electrode has been used to monitor ammonia levels in natural bodies of water and boiler water feeds. However, it suffers from significant interference from alkali metal cations and has a higher DL than the gas-sensing ISE. In general, the poor selectivity of these ISEs makes them suitable only for application in high-purity waters.

metals, they are also able to complex organic cations. The best responses are obtained for primary amines with no substituents adjacent to the amino group, e.g. 1-octylamine, dopamine and hexamine. It appears that the host–guest interaction involves hydrogen bonding between the carbonyl groups of the calix[6]arene and the protonated amino group of the organic amine. Locating the alkyl chain of the amine within the hydrophobic cavity of the calixarene further enhances the stability of the inclusion complex.

5.3 Arrays in Water Quality Monitoring

There are many ion-selective chemical sensors that can play useful roles in determining water quality. However, relatively few of these sensors can be used for the direct selective potentiometric measurements in naturally occurring bodies of water or waste effluents that contain large and widely varying concentrations of interferences. Indirect measurements can enhance the reliability and quality of the analytical information while extending the number of target analytes. However, sampling and sample pretreatment are often an integral part of these procedures. One of the most promising approaches to addressing the difficult issues of reliability, multiple analyte detection, minimum sample pretreatment, real-time monitoring, etc. is the use of sensor arrays of the type illustrated in Figure 12.\(^{(51)}\)

A sensor array for the detection of \( \text{Cu}^{2+}, \text{Pb}^{2+}, \text{Cd}^{2+}, \text{Zn}^{2+}, \text{Fe}^{3+}, \text{H}^+, \text{and Cl}^- \) has been developed.\(^{(63)}\)

![Figure 12](image-url)
Over thirty different sensor materials, mainly chalcogenide vitreous alloys, were considered. The vitreous materials exhibit good sensitivity towards their primary ion but respond significantly to the other analytes of interest. While such “cross-selectivity” would be detrimental to the performance of a single device, in a sensor array it enhances the quality of the analytical information available, allowing each sensor to provide a pseudo-independent determination of the concentration of each analyte. An important consideration when using ISEs for direct water-quality monitoring, is to consider the effects of changing temperature and pressure on the ISE response. In this regard, ISEs fabricated using incompressible solid-state materials offer improved performance and outputs that are much less sensitive to the external pressure. For example, as illustrated in Figure 13, the observed potential for a chloride-selective ISE based on a crystalline membrane of AgCl−Ag2S varies linearly with concentration over three decades of concentration even when operated with an external pressure of 10 bar.

5.4 Soil Monitoring

Metals, notably the heavy metals, can be extremely toxic and unlike hazardous organic materials cannot be broken down in the environment. Therefore, there is a strong need for simple sensors capable of providing analytical, time- and distance-dependent information about metal concentrations in soil for both protection and cleanup purposes. However, all soils contain trace levels of metal and their presence is not indicative of contamination. Moreover, while Table 7 provides information regarding the content of various metal and metal-like elements in soil, local variations can be rather dramatic. For example, the average concentration of 0.3 ppm for Se can naturally reach 1200 ppm in seleniferous soils.

Metals within soils can exist either within the soil solution or bound within the organic and inorganic components. The metals may be free (uncomplexed), e.g. Cd^{2+}, Cu^{2+}, Hg^{2+}, in various complexes, e.g. CdSO₄, ZnCl₂, AsO₄³⁻, or exist in their elemental forms. Therefore, not only is total metal concentration of interest, it is highly desirable to know bound vs free concentrations and valence states.

Soil analysis using an ISE is typically performed by either investigating samples of soil solution, i.e. collecting water runoff within the soil, or by extracting the soil into an aqueous medium. After suitable cleanup, e.g. to remove waste organic matter and humic acid, these samples can then be analyzed using the same ISE-based methods described for water samples. Several of the metals listed in Table 7, e.g. copper, cadmium, silver and lead occur at concentrations that can be directly read using an ISE. Others, e.g. mercury, require either specialized sensors capable of ultralow-level determinations, or more usually a preconcentration step.

Beyond metal analysis, nitrate determination in solids is an important application of ISEs. Concern about the intensive application of nitrogen-based fertilizers, and their potentially adverse effects on the environment, has driven the development of improved fertilizer management. Different soil-nitrate levels within a single field mean that application levels ought to be adjusted across the field to provide the optimum nutrient level for the particular crop. Use of conventional sampling and analysis techniques is not practical in this instance because

![Figure 13 Chloride-selective sensor response under the pressure and in the typical concentrations found in natural and seawater. (Reproduced from Legin et al. by permission of Elsevier Science.)](image-url)
of the cost and time required for intensive sampling. Real-time nitrate sensors make it feasible to locally map the nitrate levels within farmland, thus maximizing yields while minimizing cost and environmental impact.

### 5.5 Gaseous Environmental Pollutants

Gaseous pollutants represent one of the most formidable threats to the environment because they possess a unique ability to travel considerable and often unpredictable distances. Furthermore, substances not commonly regarded as gases may also be released into the atmosphere as aerosols, including heavy metals such as lead. Such releases represent an immediate threat through inhalation. Moreover, they can be rapidly deposited, e.g. absorbed by soil, water or plant-life. Gaseous chemicals can be incorporated into rain, e.g. dissolution of NO2 and SO2 results in destructive acid rain. Table 8 shows the more important gaseous atmospheric pollutants that can be analyzed by ISEs. The majority of gaseous tropospheric pollutants are produced as a consequence of combustion and volcanic activities.

Air monitoring presents some unique problems to the analyst as a result of the gaseous state of the analyte. Continuous monitoring is often required, making spectroscopic approaches particularly attractive. Although some ISEs are capable of performing in situ determinations of analyte concentrations in gaseous samples, the majority of ISE-based determinations involve aqueous samples. Thus, ISE-based analysis of gases is typically a batch process in which the sample is adsorbed within a solid or liquid matrix and subsequently analyzed as an aqueous sample.

Wet collection systems, usually involving buffered aqueous solutions, are employed to extract the analyte from the gaseous sample. Combinations of bubblers and diffusers provide efficient air-to-absorbant contact. This method offers certain advantages, e.g. since the samples are preconcentrated, very low DLs can be achieved in comparison to direct-reading methods. However, the ability to absorb a target analyte may be limited by the low solubility of the particular gas in aqueous media or by slow diffusion across the gas-permeable membrane, which leads to slow response times and poor selectivity.

#### 5.5.1 Carbon Dioxide

This greenhouse gas is produced ubiquitously during combustion processes. Monitoring of CO2 emissions is important for understanding its role as a greenhouse gas, for detecting rain-forest destruction, and for controlling biotechnological activities. Many very effective Severinghaus-type gas-permeable membrane electrodes are commercially available for measurement of CO2, and ISEs are the method of choice for carbon dioxide monitoring.

These sensors can determine CO2 levels either in solution or in humidified air. The probe uses glass and reference electrodes mounted behind a gas-permeable membrane such as silicone rubber. A thin film of aqueous sodium hydrogen carbonate solution separates the membrane and the surface of the glass electrode. Sample CO2 gas traverses the permeable membrane until the partial pressures of CO2 in the sample and in the internal filling solution are equal. CO2 reacts with the NaHCO3 internal filling solution to form carbonic acid. The glass electrode monitors the pH of the filling solution and the magnitude of the pH shift can be used to indirectly determine the CO2 concentration. Buffering of samples and standards below pH 4.5 is often required to ensure conversion of carbonate and bicarbonate to CO2. Because CO2 diffuses rapidly out of acidic solution, it is important to minimize the surface area of the sample, to avoid vigorous stirring and to make measurements as soon as possible after acidification.

The LOD is rather low, with a limit of $1 \times 10^{-5}$ M being observed for most electrodes. Depending on the membrane employed, this method may be prone to interferences. Microporous membranes provide little selectivity and are particularly prone to permeation of water vapor, which may swamp the electrode and produce significant drift. The most important interferences are

volatile gaseous species such as SO₂ and NH₃. While silicone rubber offers good selectivity and a high diffusion coefficient for CO₂, it is prone to interference from the passage of organic acids which may change the pH of the detector.

5.5.2 Nitrogen Oxides

NO is liberated as a product of many combustion processes but is oxidized by ambient air into NO₂. This is an extremely toxic gas at high levels and an irritant at low levels, and is a primary component of photochemical smog. The NO₂ level in air usually varies from 1 to over 100 µg m⁻³. Therefore, it is an important target analyte in environmental monitoring. An ISE using a chalcogenide glass (Se₆₀Ge₂₈Sb₁₂) as the sensing element can selectively determine NO₂ without interference from nitric oxide, sulfur dioxide, carbon monoxide, methane and other gases. However, a number of other approaches to the potentiometric analysis of NO₂ have been taken.

The traditional nitrogen oxide electrode arrangement is analogous to the Severinghaus-type gas sensor described in section 4.3. This electrode responds to dissolved nitrite or nitrous acid. In air-quality monitoring applications, the gaseous NO₂ is collected in an appropriate collection medium where it is hydrolyzed to acidic nitrite which is then detected by the glass electrode. Unlike the CO₂ electrode, the inner filling solution is unbuffered, but maintains a high nitrite concentration. The dissolved NO and NO₂, which are in equilibrium with the HNO₂ in the acidic sample, diffuse across the electrode membrane and establish an equilibrium between NO₂⁻ in the sample and electrode thin film.66

As with all Severinghaus electrodes, interference arises from the nonselectivity of the membrane to other pH-altering species. To address the problem of ISE selectivity, Meyerhoff67 replaced the glass pH electrode detector with a polymer-membrane electrode coupled to a membrane dialyzer injection loop. The NO₂ was pumped through a Teflon® membrane and trapped in an oxidizing recipient solution where it was converted to nitrite, which was then detected by the polymer-membrane electrode. This system enhanced the selectivity of NO₂ detection and was semiautomated for continuous flow. Modifying the gas-permeable membrane may also be productive, e.g. the selectivity and sensitivity of nitrite sensors is enhanced by incorporating cobalt(III)cobrinate into microporous PVC membranes.68,69

Nitrogen oxides can be chemisorbed on lead dioxide heated to 190°C to form lead nitrate which, after extraction, can be measured using a nitrate ISE. Carbon dioxide, water vapor and nitrogen do not absorb and therefore do not interfere with the measurement. However, when the sulfur dioxide concentration is more than ten times the nitrogen oxide concentration, positive errors will be observed. Nitrogen oxides can also be selectively oxidized by passing them through a 2% hydrogen peroxide solution for 24 h at a rate of 2 L min⁻¹. Unreacted peroxide is then removed by adding manganese dioxide and the nitrate level is quantified using a nitrate ISE. Unlike the lead dioxide method, even a forty-fold excess of sulfur dioxide does not interfere with the analysis.

One of the great advantages of ISEs is that their small size and portability lends itself to in situ monitoring. A personal dosimeter that first oxidizes NO to NO₂ using sodium dichromate and sulfuric acid on a glass filter, followed by further oxidation using peroxide and determination of the resulting nitrate, has been developed.

5.5.3 Sulfur Dioxide

Sulfur dioxide is an important component of air pollution and its production by power-station smokestacks is routinely monitored. The major global contribution to SO₂ comes from natural volcanic activity, and the anthropogenic contributions are produced in the metallurgical extraction industry and from the burning of high-sulfur coal. When in the troposphere, this gas actively participates in physicochemical processes such as cloud and aerosol formation, making it the major contributor to acid rain. The atmospheric concentration of SO₂ varies very significantly and can reach 5 mg m⁻³ in heavily polluted air.

Atmospheric monitoring of SO₂ is generally carried out using batch analysis, because preconcentration is required owing to the insensitivity of most analytical methods. Preconcentration is typically achieved by bubbling the gaseous sample through a buffered solution of tetra-chloromercurate(II) whose pH is maintained at a value of 6.9 to ensure quantitative adsorption. The adsorption process results in the formation of Hg(SO₃)₂²⁻.

After chemical removal of interfering nitrite (by addition of amidosulfonic acid), the solution is acidified to release the sulfur dioxide gas. A number of more selective electrodes have been reported, for example Meyerhoff et al. have detected SO₂ after reduction by bis(diethylthiocarbamato) mercury(II).70–72

5.5.4 Ammonia

Ammonia plays an active role in atmospheric pollution chemistry. It is thought to contribute substantially to atmospheric NOₓ and, as the only basic trace gas constituent of the atmosphere, it plays an important role in the chemistry of the acidic gases NO₂ and SO₂. Concentrations of NH₄⁺ and NH₃ in the unpolluted
atmosphere do not exceed a few micrograms per cubic meter. Therefore, sensors with low LODs or preconcentration are required.

The Severinghaus-type ammonia gas sensor is one of the more effective ISEs available for atmospheric monitoring. It responds very selectively to dissolved ammonia and, with the exception of volatile amines, is subject to very few interferences. Use of a PVC–nonactin composite membrane is reported to improve the analytical performance with semiquantitative detection of ammonia gas in the range 260–0.4 ppb being achieved. In the more common batch technique, gaseous ammonia is collected in an absorbing medium either directly or after adsorption onto a solid support.

5.5.5 Halides in Air

The solid-state fluoride-selective electrode is one of the earliest examples of the application of ISEs to atmospheric monitoring. Sampled air is usually passed through a collection medium and monitored by either a solid fluoride ISE or a HF gas-sensing probe. Chlorine is most commonly measured using the chlorine gas-sensitive probe, where the sensing probe is either acid- or chloride-sensitive. Airborne halide-containing acids, e.g. hydrochloric and hydrobromic acids, which ionize to yield free halide ions, both pose health risks and cause corrosion problems. In common with the analysis of metal particles in air, the halide analyte is first trapped on an impregnated filter through which the known volume of air is drawn. Cellulose acetate is commonly used as a sorbent for both particulate and gaseous halides. The halide species is extracted or wet-ashed in alkaline solution, diluted appropriately and analyzed by ISE. By using a filter to preconcentrate the analyte, the poor LODs associated with these ISEs can be circumvented and trace levels can be measured successfully.

5.5.6 Heavy Metals in Air

Typically, to perform a potentiometric determination of heavy metals that may be present in air, particulate material is first collected using a filter with a sufficiently small pore size to trap the material. A given volume of air is drawn through the filter at a predetermined rate and then the filter is digested, typically in acid. Following suitable neutralization and dilution, the filter contents are analyzed. This approach has been used to determine the concentration of mercury in air. While voltammetry is often the preferred electroanalytical technique because of its lower LODs and multianalyte capabilities, potentiometry avoids the high background signal of adsorptive stripping voltammetry due to intermetallic effects and double layer charging when attempting to determine mercury levels. The potentiometric analysis of mercury within gas samples taken from flue exhausts compares favorably with results obtained using cold-vapor AAS.

6 CONCLUSIONS AND FUTURE DIRECTIONS

A significant range of environmentally important analytes can now be determined using simple and inexpensive ISEs. The range of accessible analytes will undoubtedly continue to grow as synthetic and materials chemists devise ever more robust and selective membranes. Recent developments in ISEs, including sensor arrays, miniaturized devices, portable instrumentation and advanced ISFETs, have not yet been widely exploited in environmental monitoring. Indeed, compared with other analytical methods such as spectroscopy and chromatography, electroanalytical methods in general (and ISEs in particular), have been somewhat under-utilized. In the past, ISEs have suffered from problems of mechanical ruggedness, interferences and long-term stability. However, these difficulties have largely been solved for many analytes allowing for more routine application.

Improving the recognition chemistry is pivotal to ISEs making further contributions in the area of environmental monitoring. Research will continue to refine the selectivity using existing approaches, e.g. the ability to tune ionophore selectivity by both the nature of the substituents and the conformation of the host will continue to increase the range of target analytes. These synthetic efforts will benefit from increasingly sophisticated molecular modeling that will reduce the synthetic cycle time and increase the likelihood that highly selective ionophores will be produced. New transduction mechanisms will be exploited, e.g. phase changes, and combined detection mechanisms, e.g. optical and electrochemical signals, will be developed. Successful ISE-based environmental monitoring must be interdisciplinary and demands that instrumentation specialists, surface scientists, mathematicians, theoretical chemists and materials chemists form strategic alliances. New materials, in particular those with attractive properties (e.g. easily processed, good physical and chemical stability) for applications ranging from encapsulating materials to solid-state reference electrodes will play important future roles.

"Intelligent sensing systems" capable of recognizing and responding to changes in the concentration of environmental pollutants in a dynamic manner are likely to be an important future development. Smart sensors incorporate electronic logic, control and processing functions to offer enhanced measurement capabilities, information quality and functional performance. While these features are currently predominately found in
silicon-based transducers, they are appearing in ISEs, e.g. on-line temperature compensation.

From a fabrication perspective, the major research drive is to fabricate sensors using planar technologies. Therefore, there is intense interest in developing thin and thick films suitable for chemical sensing. Self-assembly, spontaneous adsorption, Langmuir–Blodgett and chemical vapor deposition (CVD) are all being used to produce films whose structure and chemical composition is carefully controlled and optimized for the detection of specific analytes. Miniaturization will be a recurring theme. In particular, potentiometric sensing in solids, nonpolar solvents, supercritical fluids and gases, will greatly diversify the range of environmental media in which ISEs can be successfully applied.

Soon after the invention of the laser by Maiman, laser pulses were used for excitation and ionization of sample material for inorganic analysis by optical emission spectrometry (OES) or mass spectrometry (MS). This direct approach is complicated by the complexity of the laser–sample interaction and the need to optimize simultaneously the sampling and excitation (or ionization) steps. Use of a laser for solids sampling with separate atomization and excitation in an inductively coupled plasma (ICP) retains the advantages of direct solids analysis, including spatially resolved concentration data, and adds those attributable to the ICP, including wide elemental coverage, a linear dynamic range of six or more orders of magnitude, and excellent detection limits (DLs). The resulting techniques, denominated laser ablation/inductively coupled plasma/optical emission spectrometry (LA/ICP/OES) and laser ablation/inductively coupled plasma/mass spectrometry (LA/ICP/MS), are based on recording of relative emission intensities or ion count rates, respectively. Both methods are treated here, but emphasis is given to LA/ICP/MS, a rapidly developing technique in use for less than 15 years, which in addition to offering DLs typically 10³ times lower than those obtained by LA/ICP/OES, also offers isotope ratio analysis. Hardware, analytical procedures, performance, and prospects are addressed. The power and limitations of the methods are illustrated by environmental applications, including the analysis of metals, soils, rocks, and plastics.

1 INTRODUCTION

The ICP has been used for a quarter of a century as a source for atomic emission spectrometry (AES), in which detection of element-specific optical emissions is used to determine analyte concentrations in aqueous sample solutions. The advantages of inductively coupled plasma/atomic emission spectrometry (ICP/AES) or inductively coupled plasma/optical emission spectrometry (ICP/OES), include multielemental analysis, rapid sample throughput, low noise, low background, freedom from interferences, and DLs down to the sub ng mL⁻¹ range.¹

However, ever greater analytical performance required for new applications in biomedical, geological, and environmental science led, in the mid 1970s, to searches for yet more powerful analytical instrumentation. One idea for a novel analytical technique was to marry the advantages of the ICP as an ion source with the convenience and sensitivity of MS. The resulting technique, now known as inductively coupled plasma/mass spectrometry (ICP/MS), was developed by research groups in Britain, Canada, and the USA.² Advantages of the union of the ICP ion source and the quadrupole mass spectrometer include rapid multielemental analysis, high sample throughput (up to about 70 samples per day), typical DLs in the pg mL⁻¹ range, calibration against simple aqueous standards, a linear dynamic range of seven or more orders of magnitude, relatively simple spectra, and an intrinsic isotope ratio analysis capability.³

Samples for ICP/MS analysis are introduced as an aerosol into the central channel of a torch consisting of several concentric quartz tubes. The plasma is maintained by radio-frequency power (typically about 1.3 kW) fed to a load coil near the mouth of the torch through which argon is fed. The resulting fireball is an almost perfect environment for the desolvation, volatilization, dissociation, and ionization of the sample.
 Principally singly charged cations are produced, which are extracted from the plasma at atmospheric pressure by an ingeniously designed interface directly into the low-pressure analyzer of the spectrometer.

Both ICP/OES and ICP/MS, today used worldwide for elemental analysis, are dealt with in this article. More specifically, one form of sample introduction is addressed: laser ablation (LA). However, far greater emphasis is given to LA/ICP/MS since this method is younger, developing more rapidly, and offers more prospects for innovation than LA/ICP/OES. Henceforward, therefore, LA/ICP/MS is addressed but much of the commentary also applies to LA/ICP/OES.

Samples for analysis by either of the ICP methods are usually put into aqueous solution and dispersed into fine droplets. The droplets are traditionally produced by a pneumatic or an ultrasonic nebulizer, which discharges into a spray chamber. This method is extremely successful, allowing straightforward calibration against aqueous standards and the use of internal standards to correct for any drift in instrument sensitivity. However, the defects of nebulization include temporal variation in the particle size distribution; the adhesion of certain elements, such as iodine, to the inner walls of the glass spray chamber and their later release during analysis (so-called memory effects); and low efficiency, especially for pneumatic nebulization, where around 98% of the sample solution is lost to the drain. Moreover, sample dissolution often requires lengthy (half a day or more) digestions, frequently employing potentially hazardous reagents such as hydrofluoric acid. Analytically too, dissolution introduces the possibility of the loss of volatile elements, contamination from glassware, and the unavoidable introduction of constituent elements of the reagents used, which can, in ICP/MS, produce spectral interferences in the sample analysis. For example, when hydrochloric acid is used as the solvent the species $^{40}\text{Ar}^{35}\text{Cl}$ may be produced in the plasma and be preserved in the mass spectrometer, leading to unrepresentative intensities at a mass to charge ratio ($m/z$) of 75, where arsenic is determined.

Partly in response to such difficulties, many alternative sample introduction strategies previously used with ICP/OES have been coupled to ICP/MS over the last decade. Rapid sample heating is the basis of some of these methods, specifically of electrothermal vaporization (ETV), spark ablation (SA), and LA. In ETV the sample is placed on a graphite rod and subjected to a rapid temperature ramp, resulting in vaporization of the sample into a carrier gas stream (usually argon) which transports it to the plasma. Similarly, in SA surface material is removed by the action of a high voltage spark. Advantages of ETV and SA include the ability to work with microliter sample volumes and direct solids analysis, respectively.

One of the most versatile methods of sample introduction is the use of laser pulses to mobilize sample material directly from the solid and, as with ETV or SA, entrain it in a carrier gas flow for transport to the ICP. Advantages of LA/ICP/MS encompass:

- independent optimization of the ablation and spectrometer parameters;
- little or no sample preparation;
- high sample throughput;
- very rapid semiquantitative analysis;
- reduced spectral interferences;
- spatially resolved analysis.

In the following sections the main features of the lasers used, LA systems, and laser–solid interactions are outlined. Some alternative analysis procedures are described. Specific illustrative applications of the technique to elemental environmental analysis are then given. Isotope ratio analysis is addressed separately. An overview of the analytical performance and current status of the method follows. Finally, prospects for development are assessed.

2 LASER ABLATION SYSTEMS

2.1 Laser Principles

Following the introduction of the first coherent source of microwave radiation, the maser, in 1953, attention turned to the possibility of producing a coherent visible light source – the laser (an acronym for light amplification by stimulated emission of radiation). This was achieved in 1960 by Maiman of the Hughes Research Laboratory using a ruby crystal as the active medium. A typical ruby

![Figure 1 Ruby laser with a straight flashlamp in an ellipsoidal configuration. (Reproduced by permission of John Wiley & Sons Inc., from B.A. Lengyl, Lasers, © Wiley-Interscience, p. 106 (1971).)
laser is shown in Figure 1. The elliptical reflector encloses a ruby rod and flash tube. The end surfaces of the ruby are highly polished and silvered, one end fully the other partially. The latter allows pulses of light to escape when lasing occurs. (Alternatively, mirrors external to the ruby may be used.)

Ruby consists of aluminum oxide, Al₂O₃, to which has been added a small proportion (about 0.05% by weight) of Cr₂O₃. The chromium, in the form Cr³⁺, provides the energy levels between which stimulated emission is triggered. Chromium ions in the ground state are excited to an upper energy band by an intense flash of white light from the flash tube in a process known as optical pumping. A spontaneous non-radiative transition (phonon relaxation) to a lower metastable level then occurs. As a metastable state has a relatively long lifetime, its population can be increased at the expense of that of the ground state, producing a population inversion.

Spontaneous transitions emit photons which trigger further emissions. The photons traveling perpendicular to the ends of the ruby rod build up in the resonator and are released from the partially silvered ruby face. Once started, stimulated emission depopulates the upper lasing level much faster than the pumping rate of the flash tube. Consequently, in this free-running or normal (N) mode, the light output consists of many intense spikes. Pulse widths from about 0.1 to 1 ms are typical. However, it is possible to control the output of a laser by building up such a high population inversion through use of a light seal on the active medium that when it is opened a giant pulse is produced. The quality (Q) factor of a resonator is a measure of the net energy stored. Thus rapid modification of the Q factor, by use of a shutter for example, is the key to the method known as Q-switching. The pulses so produced, known as Q-switched or Q mode pulses, have typical durations in the range 0–1000 ns. Figure 2 shows schematically the principles of production and the form of free-running and Q-switched pulses.

The ruby laser is of some interest since it was the first used to ablate solids for introduction to ICP/MS. Subsequently, neodymium:yttrium aluminum garnet (Nd:YAG) lasers have mainly been used. The energy level system of Nd:YAG is shown schematically in Figure 3. The lasing transition is between levels E₁ and E₃. As the population of E₃ is very low at room temperature, relatively little optical pumping power is required to produce a population inversion compared to a ruby system.

2.2 Laser Ablation Inductively Coupled Plasma Mass Spectrometry Hardware

A typical LA system is shown in Figure 4. The laser may be mounted as shown or in the horizontal plane, the beam being reflected onto the sample through 90° by a high-speed shutter

![Figure 2](image-url)

**Figure 2** Schematic of a ruby laser with a high-speed shutter for Q-switching. The temporal forms of N and Q mode pulses are also shown.

![Figure 3](image-url)

**Figure 3** Energy-level diagram for Nd:YAG, indicating the optical pumping and laser transitions. (Reproduced by permission of Elsevier Science from Moenke-Blankenberg, ‘Laser Micro Analysis’, *Prog. Analyt. Spectrosc.*, 9, 335–427 (1986).)

![Figure 4](image-url)

**Figure 4** Laser, ablation cell, and associated gas lines. (Reproduced by permission of the Japan Society for Analytical Chemistry from Mochizuki et al.)
mirror. Samples are placed on a stage within a glass (or quartz) cell. The stage can be moved in the $x$, $y$, and $z$ directions by a stepper-motor under computer control. The size and direction of the steps is controllable, and the laser is synchronized to fire only when the sample is at rest. A pre-selected number of laser shots are fired onto the sample surface, where rapid local heating causes the eruption of material in the form of molten droplets and vapor. Spectrometer data acquisition may be triggered by the first laser shot or after a pre-set delay. The sample surface may be viewed either by eye through a microscope equipped with a suitable protective filter or remotely via a video camera. Traditionally, visual and laser focusing are arranged to coincide.

A gas flow, usually of argon, is fed to the ablation cell via a precision flowmeter and entrains some of the ablated material, which is thus transported to the ICP. The cell is easily accessible for rapid sample exchange. However, as air must not be admitted to the ICP, a bypass valve is installed beyond the cell exit line to provide an uninterrupted flow of argon and to allow purging of the cell to atmosphere.

2.3 Laser–Solid Interactions

Owing to the complexity of the process and the large number of physical variables to be considered, the influence of the incidence of a laser pulse on a solid surface cannot be analyzed as a single problem. We may say that a portion of the incident light is absorbed to a depth of a few microns. Laser photons are absorbed by electrons in the conduction band of the material and energy is given up by collisions with other electrons and lattice phonons. As the time between collisions is much less than the shortest laser pulse, the absorbed laser energy is effectively transferred instantaneously to the solid as heat.

The rapid transfer of heat even from N mode laser pulses is enough to melt, or boil, many matrices, and material erupts from the region of impact at high velocity, forming a crater. This complex process is shown schematically in Figure 5(a) and (b). To illustrate further, scanning electron micrographs of a pit produced in nickel by a pulse from a ruby laser are shown in Figure 6(a) and (b). The crater’s edge is very well defined and the pit is roughly conical. Shots of higher energy produce larger craters with a wide region of melted material near the crater mouth. Q mode pulses of similar energy produce only a shallow surface melting.

To simplify our discussion two regimes: low and high irradiances, corresponding to irradiances of $<10^8 \text{ W cm}^{-2}$ and $>10^9 \text{ W cm}^{-2}$ may be distinguished. Very crudely these correspond to N and Q mode pulses, respectively. In the former regime, most of the material is removed as liquid, i.e. in the form of droplets. In the high irradiance regime much more vapor is produced. The gas above the sample is ionized and a plasma is formed, which in turn absorbs some of the incoming radiation and partially shields the sample surface. The complexity of the interaction is illustrated by the formation of a plasma even with N mode pulses, and this may in fact occur. As material erups from the sample in the form of a plume, complex interactions occur between it, the plasma, and the incoming laser light.

LA/ICP SPECTROMETRY IN ENVIRONMENTAL ANALYSIS

5

Figure 6 The effect of the impact of a 0.3-J N-mode shot from a ruby laser. (a) Crater produced in a nickel disc. (b) Cross-section of an ablated crater. Ablated mass $\approx 120 \mu g$. (Reproduced from Durrant.\textsuperscript{8})

Although it is always prudent to have an understanding of the underlying physics and chemistry of the ablation process as a foundation for the development of analytical laser techniques, the interactions are so complex and dependent on so many laser and sample parameters that specific experimentation is always needed. Readers interested in pursuing the subject matter of this section will find an excellent start with the review by Moenke-Blankenburg.\textsuperscript{9}

3 ANALYSIS PROCEDURES

LA/ICP/MS can provide an elemental analysis of the bulk of a sample, or some spatially-resolved data. Small spot sizes are required for the latter but not for the former. For the present, bulk analysis is treated, spatially-resolved or laser microprobe (LM) analysis being dealt with later (section 4.2).

3.1 Sample Preparation

One of the great advantages of LA is simply that samples do not have to be put into solution. Examples of preparation include selection of a fragment that fits within the ablation cell; mounting a piece in epoxy, cutting to expose a fresh surface, polishing and cleaning in methanol; pressing a powder, with or without a binder, into a pellet; production of a glass fusion. Even such limited sample preparation can bring associated problems such as contamination produced by ball-milling; or insufficient mixing with a binder, producing a heterogeneous sample. Any use of a binder also inevitably dilutes the sample. Weak laser to sample-surface coupling, e.g. between pulses from a ruby laser and pressed milk powder, may sometimes be increased by mixing the sample with a binder that shows greater absorption at the laser wavelength being used.

3.2 Optimization

The newcomer to LA/ICP/MS is faced with a bewildering array of parameters to optimize for quantitative elemental analysis. These relate to the laser, the sample, and the spectrometer. The outcome of the laser–solid interactions depends upon, among others, the wavelength, energy, mode, focusing, and angle of incidence of the laser beam. Wavelengths of 694 nm [ruby], 1064 nm, 532 nm (frequency doubled), 266 nm (frequency quadrupled) [Nd : YAG], and 193 nm [F excimer] have been employed, with the historical trend towards shorter wavelengths, i.e. from infrared (IR) to ultraviolet (UV), for more precisely controlled LA. Generally, however, the light wavelength is determined by the laser hardware and is therefore fixed for any specific laboratory system. Greater laser energies generally produce greater ablated mass and therefore greater responses. Laser shot energies may be varied by the use of beam filters or masks.

As already noted, the ablation process is strongly influenced by the use of N or Q mode pulses. The latter vapor-producing pulses should theoretically produce less fractionation, i.e. the selective removal from the sample of one element relative to another. However, such pulses, being extremely intense and rapid, sometimes produce memory effects by vaporization or re-suspension of material previously deposited in the ablation cell and transport tubing. Moreover, Q mode pulses are associated with an acoustic shock which is transported to the ICP, decreasing the reproducibility of the analytical signal. Such deleterious effects may be partially offset by the use of multiple low-energy (mJ) pulses at high repetition rates, e.g. 10 Hz, and such schemes have been practicable since the introduction of Nd : YAG lasers.

Focusing of the laser beam is an obvious parameter of interest. Both surface- and off-surface focusing have
been employed: the former to increase ablated mass and spatial resolution; the latter to deliberately reduce these for particular applications.

The angle of incidence of the laser beam will influence the complex plasma shielding produced above the sample. Thus instead of normal incidence an angle between the beam and the sample surface of 45° is sometimes employed.\(^6\)

Unfortunately, the ablation process depends not only on the laser parameters but also on the nature of the sample – its color, reflectivity, thermal conductivity, mineralization, and so on. Indeed, it is just such dependencies that form the Achilles’ Heel of fully quantitative analysis by LA/ICP-spectrometries. For our purposes one example of the difficulties involved in quantitation will suffice. Figure 7 shows the size distribution of droplets produced by ablation of stainless steel. Only droplets of a few microns in diameter will be transported to the ICP. Therefore, a shift in the size distribution, for example between ablation of a sample and a standard, will directly influence sample transport and hence the count rate measured by the spectrometer, leading to errors in quantitation.

Finally, the spectrometer parameters should be optimized. To maximize elemental responses the cell flow and ion lens voltages may be systematically varied while monitoring the \(^{12}\text{C}^+\) signal, which appears to be due to the presence of CO\(_2\) in the Ar flow. This procedure is simple but truly optimal performance is ensured only by using realistic conditions, such as the continuous ablation of a solid of known composition. A subtle complication is that varying the cell flow alters scavenging as well as the optimal sampling depth (torch to sampling cone separation), so that the latter should also be systematically studied.

Owing to considerations such as these, extensive systematic studies are very time-consuming, though some have been reported.\(^8,^{10}\) The requirement for multielemental analysis is sufficient sensitivity for the determination of the proposed analytes and the best practicable reproducibility. Higher laser energies ablate more sample and so give higher count rates, but excess ablation leads to the deposition of excess material in the cell and exit line, often leading to memory effects. Also, excess ablation will first cause a saturation of the counts of individual matrix elements, which may not be seriously detrimental to the analysis. However, higher rates of sample ablation will cause plasma disequilibrium, disrupting the ionization process in the ICP and preventing quantitation. Thus a set of compromise conditions must be found.

### 3.3 Quantitation

We may note first that quadrupole spectrometers collect data at specific \(m/z\) values (peak hopping) or across a range or set of ranges of \(m/z\) (scanning). As continuous exposure to very high count rates may damage the detector, any permanently saturated peaks, such as that of \(^{40}\text{Ar}^+\), are deliberately skipped.

Before specific calibration procedures are considered, brief mention is made of blanks and DLs. In solution nebulization/inductively coupled plasma/mass spectrometry (SN/ICP/MS) a blank spectrum obtained from an analysis of the solvent (typically 2% v/v HNO\(_3\)) is usually subtracted from any sample spectrum. The most rigorous procedure for LA/ICP/MS is to produce a blank spectrum by ablation an inert target such as poly(tetrafluoroethylene) (PTFE) since this exactly simulates the sample analysis. The DL, a measure of the minimum detectable concentration, is defined as 3SDs of the blank. Either this definition or, perhaps more realistically, the line equals background equivalent concentrations for a blank may be used in LA/ICP/MS.

A single laser pulse produces a transient response, typically of 20 to 30s, depending on the cell flow rate. The peak height or area may be used for quantitative analysis, but this approach is generally inferior to the use of the more stable response generated by multiple pulses of low energy, which yields better analytical precisions. Typical responses from multiple laser pulses are shown in Figure 8. Multielemental analyses based on transient responses are also impeded because of the need for rapid scan rates from the quadrupole spectrometers.

Rapid survey analysis was always possible by LA/ICP/MS,\(^6\) but to obtain precise and accurate elemental concentrations is the principal challenge to researchers in the field. A semiquantitative analysis requires a standard containing a few known concentrations. A response versus mass curve is then produced (using the sensitivities

from the known elements and correcting for isotopic abundance) as shown in Figure 9. This has the advantage of allowing determination of elements not certified in the standard, but usually at the expense of reduced accuracy.

Simple element-for-element calibration against the sensitivities of individual elements of known concentration in an external standard has been employed.[14] For better accuracy and precision the standard has to have a similar structure and composition, i.e. the sample and standard are matrix-matched. Alternatively, a full set of well-characterized external standards may be used to obtain plots of response versus concentration. All laser and spectrometer parameters are kept constant for analysis of the samples and standards. Obvious difficulties include the non-availability of suitable standards and the expense of extensive use of standard reference material for calibration. In addition, standards are often inadequately characterized: elements of interest have not been determined or only “guidance” concentrations are given, or elements are certified at extremely low concentrations which do not provide sufficient counts for useful calibrations. Artificial standards made, for example, by adding aqueous standard solutions to a suitable matrix, drying, mixing, and pressing into pellets are sometimes successfully employed.

Internal calibration using responses obtained from elements in the sample itself may be used, requiring an independent determination of the concentration of a few elements in the sample.

Other approaches include external calibration on sensitivities obtained from the nebulization of standard aqueous solutions,[10] though this involves the loss of the advantage of working with a dry plasma, namely a reduction in spectral interferences. To overcome just such complications, internal standards[11] have recently been introduced to the outlet of an ablation cell by ETV. Similarly, Günther et al.[14] retained the advantages of calibration against solution samples by using a dual desolvation/LA system for the determination of rare earth elements (REEs) in soil, bentonite, and synthetic polyethylene, obtaining precisions of <10%.

Internal standardization is widely used in SN/ICP/MS to improve analytical precisions. In LA/ICP/MS its use is indispensible since differences in laser energy, surface texture, and so on, ensure that the ablated sample mass is not constant even for sequential analyzes. Normalizing the responses to that of a known element, usually a minor isotope of a major constituent, corrects for this type of variation. Between replicate internal standardization is easily performed because it does not require knowledge of the concentration of the element used. The procedure may be applied between the standard and the sample if the concentrations of an element are known in both.

4 APPLICATIONS IN ENVIRONMENTAL ELEMENTAL ANALYSIS

The specialty steels used in the construction of petroleum and petrochemical plants must be within the specifications for elemental composition if they are not to pose a safety hazard. Integrated electronics are now of such small dimensions that $\alpha$-particle-induced damage is a serious problem, necessitating the use of aluminum wiring with U 7440-61-1 and Th 7440-29-1 impurities of <1 ng g$^{-1}$. Knowledge of the concentration and distribution of elements in peridotites and their constituent minerals is essential to understanding the chemical evolution and composition of the lithospheric mantle. Such are

the challenges that LA/ICP/MS must meet. Illustrative applications are given below.

4.1 Metals

Metals are a logical starting point for study of the efficacy of LA/ICP/MS since they may be considered “liquid solutions” of uniform composition unless spatial resolution to the size of metal grains is considered. An example of the quantitative analysis of steels based on sensitivities obtained from a suite of steel standards is given in Table 1. As there are many characterized steels, this approach is more practicable than for other types of matrix. The sample was ablated using a 5 × 5 raster of points, covering a sample area of about 9 mm². Each crater was ablated five times with Q mode shots from a Nd : YAG laser at a repetition frequency of 4 Hz. Five such measurements were made per sample. Accuracies and precisions were typically <10% and DLs in the range 1–100 µg g⁻¹.

Additional examples of metals analysis are documented in Table 2.

4.2 Geological Materials

The difficulty of summarizing a large and rapidly growing literature is especially acute for geological applications. Several major themes, however, may be discerned: elemental analysis; fingerprinting; microprobe studies. Isotope ratio analysis, another active area, is dealt with separately in section 5.

Summaries of a number of studies of the determination of major, minor, and trace elements in matrices such as soils, silicates and carbonates are given in Table 3. Early studies using ruby lasers for ablation included the analysis of basalt and Chinese reference soils. A spectrum reproduced from the former shows the responses obtained for the REEs, Th and U (Figure 10). The peak integrals ranged from 150 to 4800 counts for the analyte isotopic concentrations of 0.16 to 5.8 µg g⁻¹. In the second study the elements Na (7440-23-5), Mg (7439-95-4), Al (7429-90-5), Ca (7440-70-2), Sc (7440-20-2), Ti (7440-32-6), V (7440-32-6), Cr (7440-47-3), Mn (7439-96-5), Fe (7439-89-6), Co (7440-48-4), As, Rb (7440-17-7), Sb (7440-36-0), Cs (7440-46-2), Ba (7440-39-3), La (7439-91-0), Ce (7440-45-1), Nd (7440-00-8), Sm (7440-19-9), Eu (7440-53-1), Dy (7429-91-6), Ho (7440-60-0), Yb (7440-64-4), Hf, Ta, W, Th and U were determined in seven soils. Precisions were typically in the range 2–10% RSD, but some were considerably poorer for elements present at trace concentrations. DLs were as low as 0.1 µg g⁻¹ for many elements.

Often the objective of an analysis is identification of the source of the material and this does not require full quantitation. “Fingerprinting” of gold, steel from safes, and glasses, for example, is possible. The method relies on the identification of patterns of elemental responses as illustrated in Figure 11 for three separate analyses over three months of steel from five safes; four groups of elements are compared. These so-called ternary plots represent the direct comparison of the relationship between three components in a system. For data to plot in any corner of a triangle, representing the ternary association of the three components, would indicate that the concentration of that component indicated at the corner was 100% relative to the other two components.

While samples with different provenance will be discriminated in ternary plots by a suitable choice of analytes, samples with the same provenance will not be discriminated under any variation of analytes. The plots of Figure 11, for example, show a tight packed relation for safes 3 and 5 in all but the last (lower right), the latter indicating a different provenance. This fingerprinting technique has already proved a practical success in forensic science.

The ability to provide spatially-resolved analysis is one of the anticipated advantages of LA/ICP-spectrometry, and has been markedly improved over the last ten years. Ablation by single laser shots, multiple shots on the same site, individual sites in a row or in a plane in principle allow the analysis of individual grains, the production of

RSD, relative standard deviation.

depth profiles, line profiles, or area analyses, respectively. Of major importance to the analytical performance of laser microprobe/inductively coupled plasma/mass spectrometry (LM/ICP/MS) is the spatial resolution. Some of the early studies in which improved laser optics allowed the ablation crater diameter to be reduced from 150 µm to about 25 µm are briefly reviewed elsewhere.\(^{33}\)

Moissette et al.\(^{34}\) used pulses at 266 nm from a Nd: YAG laser operated at 10 Hz to ablate synthetic fluid inclusions in halite, microwells containing aqueous solutions, and glass reference materials. In this field, elemental intensities are reported as ratios to Na but owing to difficulties in measuring this element were reported ratioed to Sr (7440-24-6). Elemental ratios for Li (7439-93-2), Mg, K (7440-09-7), Ca, Mn, Cu (7440-50-8), Zn (7440-66-6), Rb, Cs, Ba, Pb (7439-92-1), B (7440-42-8), Cl (7782-50-5) and Br (7726-95-6) in the synthetic fluid inclusions were linear over several orders of magnitude.
magnitude and in close agreement with those for the NIST SRM 611 glass and microwell solutions, irrespective of the inclusion size (20–100 µm) and depth in the sample (up to 80 µm). Thus microwells and glasses constitute suitable alternatives to synthetic fluid inclusions for the calibration and routine analysis of natural fluid inclusions. Similarly, concentrations for Sr in the range 90 to 153 µg g⁻¹ and Rb (98 to 100 µg g⁻¹) were determined in large (up to 1 mm diameter) fluid inclusions in halite with precisions of 5–31%.
Further improvement in analytical performance is expected from the use of excimer lasers with wavelengths below 200 nm. The output from these devices gives extremely well-defined ablation pits and is also expected to produce less severe fractionation effects. Successful application of such instruments requires more sophisticated laser optics than used hitherto. Such a system, incorporating an argon fluoride 193 nm excimer laser, has been mounted, with a common UV/visual objective on a modified petrographic microscope with reflected and transmitted light illumination.\(^{36}\) The improved beam quality allows the ablation of pits of only 4 µm diameter, giving DLs of <10 µg g\(^{-1}\) for selected elements between Rb and U.

### 4.3 Biological Materials

The author and colleagues reported the bulk multielemental analysis of botanical material\(^{37}\) and foodstuffs.\(^{38}\) To illustrate the sensitivity even of early ruby laser and quadrupole instruments, Figure 12 shows a spectrum obtained by ablating NIST 1577a bovine liver with 10 1.4-J N-mode shots. Mercury and lead were present at 4 and 135 ng g\(^{-1}\), respectively. The isotopes of Hg (7439-97-6), Pb, and Bi (7440-69-9) are clearly visible.

LM analysis (variously abbreviated in the literature as LM, LAM, or LAMP) now offers more sophisticated possibilities. Outridge and Evans,\(^{39}\) for example, outlined the difficulties encountered in analyzing teeth with ablation by pulses of wavelengths of 532 and 266 nm, finding that the analysis is wavelength, beam energy, and matrix dependent. More successful was a minor and trace element analysis across the growth bands of a shellfish *Arctica islandica*, with the resulting elemental profile being used as an indicator of heavy metal pollution through time. A spatial resolution of <10 µm was provided by the UV laser employed.\(^{40}\)

The improved analytical performance of LM/ICP/MS over the last five years has apparently been little applied to biological analyses and is open for exploitation. Table 4 summarizes key features of studies of biological materials.

### 4.4 Polymers

Analysis of plastics is illustrated by the early work of Marshall et al.\(^{42}\) Successful analysis of polyester and polypropylene is demonstrated by the concentration data, reproduced in Table 5.

Improvement in analytical figures of merit can be expected with the use of the latest laser technology. This has been shown for the determination of Al, Ba, Ca, Cd (7440-43-9), Mg, Sb, Sn (7440-31-5) and Ti in poly(vinyl)chloride using LA/ICP/OES by Mermet’s group,\(^{43}\) where DLs obtained using a UV laser compare favorably with those obtained by SN/ICP/OES.

### 4.5 Other Matrices

Table 6 gives details of the analysis of diverse matrices by LA/ICP/OES and LA/ICP/MS. In nuclear applications where analysis of radioactive or toxic materials is common a complete LA/ICP/MS system may be sealed in a glove box. Laser sampling may readily be performed

far from the spectrometer since extending the laser cell to spectrometer tubing produces very little reduction in analyte responses.

5 ISOTOPE RATIO ANALYSIS

Isotope ratios may readily be determined by SN/ICP/MS. Factors of importance in such determinations include:

- sensitivity and counting statistics
- dead time
- resolution and abundance sensitivity
- mass bias.

Thus count rates well above background are required, but these must not be so high that the detector is overwhelmed. However, to a degree, a dead-time correction can be applied at the onset of saturation, thus extending the working concentration range. Peaks nominally one mass unit apart must be clearly resolved, but resolution improves at the cost of sensitivity, so over-resolution is to be avoided. In practice, trailing of one peak into an adjacent peak also occurs and sufficient abundance sensitivity, as it is known, to resolve a small peak from an adjacent intense one is necessary. In addition, the measured isotope ratio may deviate from the true value as a function of the difference in mass between the two isotopes measured. This effect, known as mass bias, may
be measured by comparison with a standard of known isotopic composition.

Owing to these considerations and to the ICP being a fairly noisy source, the best precisions achievable by SN/ICP/MS are typically 0.1% RSD. Unfortunately, the addition of signal fluctuations associated with sample introduction by LA leads to even poorer precisions, rendering useful isotopic ratio measurements by LA/ICP/MS extremely difficult.

In 1987, Tye et al.\textsuperscript{(54)} reported the measurement of the ratios $U$\textsuperscript{234} : $U$\textsuperscript{235} , $U$\textsuperscript{234} : $U$\textsuperscript{236} and $U$\textsuperscript{235} : $U$\textsuperscript{236} in $U_2O_4$ with percentage RSDs of 1.340, 0.774 and 1.020 respectively.

Subsequent improvement in laser optics allowed the determination of $^{207}$Pb : $^{206}$Pb ratios and hence the calculation of ages of zircons with a grain size of >60 µm and a $^{207}$Pb concentration of >3 µg g$^{-1}$, to within 1% of the ages determined from thermal ionization mass spectrometry (TIMS) measurements.\textsuperscript{(55)} Precisions for the average of the mean $^{207}$Pb : $^{206}$Pb ratios from different pits in one grain were generally <1.5%. Although $U$ : Pb ratios could not be accurately or precisely determined by LM/ICP/MS, its performance was otherwise comparable to the specialized technique usually used for such measurements, namely the sensitive high-resolution ion microprobe (SHRIMP).

Relatively poor precision is the stumbling block to the wider useful application of LA/ICP/MS to isotope ratio measurements but is overcome by the use of more sophisticated high-resolution spectrometers. In magnetic sector instruments the sampling interface is held at a high potential, e.g. +8 kV, and the quadrupole analyzer is replaced by an electrostatic and a magnetic analyzer, which transmit ions by kinetic energy and $m/z$, respectively. Following this double focusing the transmitted ions are detected by a Faraday cup (or cups).

An up-to-date, simple and concise introduction to such spectrometers is available.\textsuperscript{(56)}

Use of LA with a magnetic sector mass analyzer equipped with seven Faraday detectors\textsuperscript{(57)} allows the determination of Pb isotope ratios with precisions comparable to those obtained by TIMS.\textsuperscript{(58)} In this analysis the isotopic composition of lead within NIST SRM 610 glass was measured using Q mode pulses of 2 mL from a Nd : YAG laser for sample ablation. Craters of <40 µm diameter were produced, corresponding to a total ablated mass of Pb of about $9 \times 10^{-11}$ g per crater. Simultaneous measurement of $^{202}$Hg, $^{203}$Tl, $^{204}$Hg and $^{204}$Pb, $^{205}$Tl, $^{206}$Pb, $^{207}$Pb, and $^{208}$Pb isotopes was made. As the ratio $^{205}$Tl : $^{203}$Tl had previously been shown to be related to the mass bias, this ratio was measured and used to correct the measured lead isotope ratios. The response of an isotope of mercury, $^{204}$Hg, overlapped with that of $^{204}$Pb but was corrected by measurement of the $^{202}$Hg isotope. Table 7 shows the lead isotope ratios for repeat analyses, together with the standard error. The mean and standard deviation of each set is also given and compared with data obtained by TIMS and, where available, by secondary ionization mass spectrometry (SIMS). The important feature of the data is the precision, which is comparable to that obtained by the traditional methods of choice for such analyses.

Although not illustrated by the above analysis, high-resolution spectrometers are often also able to resolve out interfering polyatomic species. For example, a resolution of 2500, defined as the mass $M$ divided by the mass width $\Delta M$, resolves $^{56}$Fe$^+$ from $^{40}$Ar$^{16}$O$^+$, thereby allowing determination of iron at $m/z$ 56.

Another innovative approach to isotope ratio determinations was reported by Houk et al.\textsuperscript{(59)} using a double quadrupole instrument. The rationale for such an instrument is to eliminate flicker noise from the LA process by splitting the ion beam into two, each part being sent to its own quadrupole mass analyzer and detector. The sample was ablated with pulses from a Nd : YAG laser frequency doubled to operate at 532 nm and operating at

15 Hz and about 70 mJ per pulse. Count rates obtained simultaneously at m/z 52 and 53 from the ablation of NIST SRM 1263 showed an RSD of 3%, but for the ratio of the two signals the RSD improved to 0.54%. When five consecutive ratios were averaged, the average of five such averaged ratios was 0.24%. The latter was improved to 0.058% by increasing the dwell time (the time spent in accumulating data) from 0.5 to 2.0 s. Such precisions, of ratios of isotopes of one element, are only slightly above the counting (Poisson) statistics limit.

**6 PERFORMANCE AND STATUS**

As we have noted, the anticipated advantages of LA/ICP/MS and LA/ICP/OES include little sample preparation, rapid sample throughput, and excellent DLs. Occasionally no sample preparation is needed and this represents an enormous saving in the workload of a skilled analyst. Frequently, however, some sample manipulation is required for maximum analytical performance. Throughput, i.e. the number of samples analyzed per working day, is excellent, being at worst equal to that of SN/ICP/MS. The DLs achieved are element and matrix specific but are now <1 µg g⁻¹ for ablated crater diameters of only 20–40 µm.⁶⁰

Another anticipated advantage of LA/ICP/MS with a quadrupole spectrometer is a significant reduction in spectral interferences owing to a reduction in the water loading of the ICP. This reduces water-derived polyatomic species present below mass 80 in SN/ICP/MS analyses as indicated by the data of Mochizuki et al.⁷¹

Table 8 Comparison of background intensities obtained by LA and solution introduction methods

Presented in Table 8. (The Ar dimers are not water-related and levels are essentially the same in both SN/ICP/MS and LA/ICP/MS).

The linear dynamic range of ICP spectrometry is so familiar to users that it is perhaps overlooked. When pulse counting and current detection are both used, as they are in some ICP/MS instruments, for low and high count rates, respectively, the linear dynamic range extends over seven orders of magnitude or more.

Difficulties in obtaining fully quantitative concentration data have been apparent since Gray's original feasibility study.⁵英格尼斯 methods of calibration and internal standardization have been developed, and improved precisions are obtained by the use of radiation in the UV or far UV instead of the IR. Figures of merit are further improved by the use of magnetic sector instruments, which are now in much wider use than in the early years following their introduction in 1988.

One contribution to inaccuracy and imprecision, however, has not been fully overcome, namely chemical fractionation. Some studies of this effect have been undertaken. For example, elements such as Nb (7440-03-1), Ta, Zr (2440-67-7), and Hf show decreased fractionation trends with respect to Si in NIST SRM 610 glass during repeated LA, while elements such as Rb, Sr, Pb, Ba, and Ca show increasing trends. The effect, greater for IR than for UV/LA,⁶¹ may be due in part to the formation of a complex plasma which both ablates the sample and shields it from incoming laser light. In a comparison of the ablation of glass by pulses of wavelength 1064 nm (IR), 532 nm (green) and 266 nm (UV), elemental fractionation was dependent on the melting point of the elemental oxide only for the first two wavelengths.⁶²

Relatively little fractionation may occur with ablation by excimer lasers,⁶³ though the evidence is not definitive and more studies are needed. Indeed, an important observation by Outridge et al.⁶⁴ is that fractionation may occur not only in ablation but also in the transport of material to the ICP. Thus many of the previous studies of this problem have concerned only the product of these two effects and are therefore somewhat inadequate.

Finally, LA/ICP/OES deserves mention. Generally, this technique is less sensitive than ICP/MS and does not offer isotope ratio measurements. Against this should be set its greater simplicity of operation and maintenance and lower capital cost. Moreover, ICP/OES is also less prone to matrix effects than ICP/MS. In short, LA/ICP/OES is a very powerful technique and has received relatively little attention here only because of the relative strength of LA/ICP/MS. It should also be noted that most of the comments given concerning LA/ICP/MS also apply to LA/ICP/OES. For example, fractionation leads to a sample unrepresentative of the
original material and this influences either technique. In contrast, polyatomic interferences are a problem specific to ICP/MS.

7 DEVELOPMENT PROSPECTS

Means to improve analytical performance in LA/ICP/MS will continue to be developed. The wider use of mixed-gas plasmas, for example, would be advantageous in LA/ICP/MS to increase sensitivities and reduce relative oxide levels. A new soft ablation technique in which a slowly ramped increase in laser power produces a smoother response profile has given Pb:U age data in excellent agreement with those obtained by TIMS and SIMS. The improvement in performance, attributed to reduced fractionation effects, clearly merits further study.

Perhaps the most exciting foreseeable developments, however, lie in alternative spectrometers. We have already met double quadrupole instruments, but these are likely to remain a research tool in selected laboratories only. Other candidates include Fourier transform ion cyclotron resonance (FTICR), ion trap (IT), and time-of-flight (TOF) instruments. The possible use of such systems is outlined by Hieftje et al., who also indicate why inductively coupled plasma/time-of-flight/mass spectrometry (ICP/TOF/MS) may be the most promising among them. A prototype instrument has already been used in conjunction with LA. Indeed, this technique has recently been applied to the analysis of metals. Here we may note that the advantages of ICP/TOF/MS include high ion transport efficiency, high sensitivity, and extremely fast (<60 µs) spectral collection across the whole mass range.

The reader is also directed to other exciting applications of LA/ICP/MS indicated by recent literature, namely biological speciation and archeological studies. As we have seen, successful applications of LA/ICP/MS and LA/ICP/OES abound in metallurgy, geology, materials science, pollution studies, nuclear science, and so on; both techniques deserve greater attention from botanists, biologists, and medical scientists.

Concerning the development of new instrumentation, alternative analytical procedures, and novel applications, the next decade promises to be even more exciting than the last.

On-line liquid chromatography/mass spectrometry (LC/MS) has become a powerful technique in environmental analysis because of the separation capabilities of liquid chromatography (LC) and the detection and identification potential of mass spectrometry (MS), the characteristics of both methods making coupling very attractive. Among the interfacing systems used to couple LC with MS, those based on the atmospheric pressure ionization (API) offer advantages in terms of sensitivity and capability to analyze highly polar, ionic, heat sensitive and high-molecular-weight substances. Further, the on-line coupling of chromatographic separations with element-selective detection systems such as inductively coupled plasma mass spectrometry (ICP/MS) is an attractive technique for trace element speciation.

The main advantage of LC/MS lies in its ability to provide qualitative information (including molecular mass and fragmentation pattern) on the detected peaks. In addition, when all the ionization parameters are optimized, quantitative analyses can be carried out and low detection limits (at the ppb level) are obtained performing selective ion detection.

In environmental analysis, universal, selective and sensitive methods are needed to afford the assay of a wide variety of target and nontarget substances. Even though gas chromatography/mass spectrometry (GC/MS) is extensively applied to the analysis of organic contaminants in several matrices, LC/MS offers major advantages over GC/MS for analyzing polar, nonvolatile and thermolabile compounds. Ultraviolet (UV) or diode-array detector (DAD) are commonly used to perform detection in high-performance liquid chromatography (HPLC). However, UV-based detection methods for HPLC have several disadvantages deriving from nonspecific detection and lack of sensitivity. A more reliable identification is sometimes possible using DAD for certain compound classes, e.g. nitrophenols, in environmental samples; however, structural information is lacking for some classes of pollutants, among which are some pesticides, because their UV spectra are often almost identical. Using unspecific LC detectors, detection may be complicated by false-positive results; in such cases, MS has proved to be an extremely valuable technique for unequivocal identification of microcontaminants in a variety of environmental samples.

This overview discusses recent instrumental developments concerning mass analyzers of the mass spectrometers and on-line sample treatment procedures, with emphasis on the environmental field. Among the environmental applications of LC/MS, methods for the analysis of pesticides, polycyclic aromatic hydrocarbons (PAHs), dyes, surfactants, inorganic and organometallic compounds in environmental samples are discussed.

1 INTRODUCTION

High-performance liquid chromatography/mass spectrometry (HPLC/MS) realizes the combination of an analytical liquid-phase-based separation with mass spectrometric analysis for determination of nonvolatile, polar, thermolabile and ionic compounds.

On-line LC/MS has become a powerful technique in qualitative and quantitative analysis also in the environmental field because of the separation capabilities of LC and the detection and identification potential of MS, the characteristics of both methods making coupling very attractive.
The interfacing of LC with MS has been the object of fervent research for almost 30 years, since the first studies of Tal’roze et al. in 1969. Different approaches have been devised to provide an effective combination of these two techniques including direct liquid introduction (DLI), moving belt (MB), particle beam (PB), thermospray (TS), continuous-flow fast atom bombardment (CFFAB) and more recently electrospray (ES), pneumatically-assisted electrospray (PAES) or ionspray (IS) and heated nebulizer/atmospheric pressure chemical ionization (HN/APCI). Finally, the on-line coupling of chromatographic separations with element-selective detection systems such as ICP/MS is an attractive technique for trace element speciation.

LC/MS has progressed rapidly in the last years because it has benefited from the marked development of atmospheric pressure MS sources utilizing ES ionization; these ionization techniques are capable of producing ions from highly polar, ionic, heat sensitive and high molecular-weight substances. The main advantage of LC/MS is its ability to provide qualitative information (including molecular mass and fragmentation pattern) on the detected peaks. In addition, when all the ionization parameters are optimized, quantitative analyses can be carried out and low limits of detection (LOD) (at the ppb level) are obtained performing selective ion detection; selective ion monitoring (SIM) acquisition is a useful approach to obtain maximum sensitivity in the quantitation of target compounds.

In environmental analysis, universal, selective and sensitive methods are needed to afford the assay of a wide variety of target and nontarget substances. Even though GC/MS is still the most popular technique for the analysis of toxic organic micro-contaminants in several matrices, LC/MS offers major advantages over GC/MS for analyzing polar, nonvolatile and thermolabile compounds. Conventional detection in HPLC is usually achieved with UV or DAD. However, UV-based methods of HPLC have several disadvantages deriving from nonspecific detection and lack of sensitivity. The most serious drawbacks of UV detectors arise from matrix interferences particularly when working at low wavelengths, since several compounds lack a strong chromophore in the UV region for sensitive detection. When using DAD, a more reliable identification in environmental samples is sometimes possible for certain compound classes, e.g. nitrophenols. However, structural information is lacking for some classes of pollutants, for example, some pesticides, because their UV spectra are often almost identical. Therefore, UV detection and DAD are not well suited for universal application. If unspecific LC detectors are used, detection may be complicated by false-positive results; in such cases, MS has proved to be an extremely valuable technique for unequivocal identification of micro-contaminants in a variety of environmental samples.

1.1 Mass Spectrometers: Characteristics and Recent Developments in Mass Analyzers

Recent instrumental improvements to LC/MS systems are related to the use of mass analyzers instead of the quadrupole mass spectrometers.

Quadrupole instruments are the most common in LC/MS applications in various research areas and also in the environmental field; the relatively low costs, the ease of operation and fast data acquisition account for the widespread use of this mass analyzer. Other features of the quadrupole are the adequate dynamic range, the unit-mass resolution and the good quantitation capabilities; the restricted mass range (up to 4000 Da) is the main drawback, even though it is not a problem in environmental analysis.

Quadrupoles are readily combined with other types of analyzers, including other quadrupoles in arrangements for tandem mass spectrometry (MS/MS) experiments; triple quadrupole mass spectrometers are used in MS/MS for enhanced selectivity and improved detectability in trace analysis. This subject will be discussed in the section 1.3.

Commercial LC/MS instruments are also based on ion trap (IT) technology; interesting features of an ion trap mass spectrometer (ITMS) are the high sensitivity due to ion accumulation capabilities (100 times higher than by scanning quadrupole MS), the specificity because of the MS/MS options, the unlimited mass range and the scanning speed. On the other hand, IT systems generally suffer from space charge effects, ion–molecule reactions and from a limited dynamic range. Multiple-stage tandem mass spectrometry (MSN) experiments which can be performed with this mass analyzer make the ITMS attractive particularly in structure elucidation rather than in quantitative target compound analysis. It should be noted that commercial IT-based LC/MS instruments are considerably less expensive than triple quadrupole systems and thus they could be ideally suited for target-type screening procedures in environmental applications.

Another mass analyzer which shows good perspectives in environmental LC/MS analysis is the time-of-flight (TOF) instrument. Time-of-flight mass spectrometry (TOFMS) can provide high sensitivity and a fast acquisition rate, combined with higher mass accuracy compared with scanning techniques such as quadrupole MS; the last feature is especially important for high-resolution capillary separation methods, such as capillary HPLC and capillary electrophoresis. Since it is a non-scanning instrument, mass resolution is not related
to sensitivity, so that high sensitivity can be achieved with a reasonably high resolution. TOFMS can be used in combination with pulsed ion sources, such as matrix assisted laser desorption/ionization (MALDI) making this system particularly useful in biological applications where high-molecular mass compounds are to be analyzed.

The magnetic sector mass spectrometer is used in environmental applications which require very high resolution, to aid structural elucidation and confirm molecular formulae of toxic micro-contaminants. Besides accurate mass measurements, this instrument can provide several benefits such as good sensitivity and selectivity and an excellent dynamic range. The high costs of the equipment, the complexity of operation are the main drawbacks of the magnetic sector mass spectrometer. Further, because of the high vacuum requirements, the combination of this mass analyzer with high-pressure LC/MS interfacing/ionization systems is not ideally suited; in fact, the enhancement in sensitivity due to improved ion transmission efficiency in the sector falls off because of losses in ion transmission in the passage from the high-pressure ion source to the high-vacuum analyzer.

High-resolution measurements are achievable with the Fourier transform ion cyclotron resonance (FTICR) instrument; the exact mass assignment capabilities, the excellent sensitivity and the feasibility of performing multiple-stage MS/MS are outweighed by the high prices and the severe vacuum restrictions of this sophisticated mass analyzer. For these reasons, it is rarely used in environmental applications and is unlikely to be employed widely in this field in the future.

### 1.2 Chromatographic Mechanisms and Solvent Systems

**Liquid Chromatography/Mass Spectrometry**

LC/MS coupling often puts restrictions on LC flow rate or mobile phase composition. The eluent flow-rate plays a very important role in interfacing to MS. As for PB, the acceptable liquid flows vary in the 100–1000 μL min⁻¹ range according to the different nebulizer designs. With the TS interface the total effluent from a conventional HPLC column (over 1 mL min⁻¹ of an aqueous mobile phase) can be introduced directly into the MS vacuum system. Interfaces such as CFFAB and ES can accommodate only limited flow-rates (about 5 μL min⁻¹), whereas IS is capable of operating at 50–100 μL min⁻¹ thanks to the independent pneumatic nebulization; for this reason, in research to develop the various LC/MS interfacing systems, considerable attention has been paid to miniaturization of the HPLC columns to obtain the required linear velocity, without the need for conventional post-column splitting for flow-rate reduction. On the other hand, various manufacturers have proposed the introduction of higher flow-rate ES interfaces, such as turbo-ionspray™ (Perkin-Elmer Sciex trademark), ultrasonically assisted ES, thermally assisted ES and various high-flow options to be used in combination with pneumatically assisted ES; these instrumental developments with reference to commercially available LC/MS interfaces are extensively discussed in a recent review paper.

Among the API techniques, HN/APCI offers high solvent flow-rate capability (up to 2 mL min⁻¹); further, this interface/ionization system is compatible with a variety of mobile phase compositions, including pure aqueous solvents, making this technique highly versatile. The need for using volatile buffers with the other interfaces is a serious drawback, since chromatographic mechanisms, such as ion-exchange and ion-pair (IP) LC, which are useful for separating analytes which are also of environmental concern, cannot be universally applied. A possible solution to the requirements of volatile buffers and ion-pairing agents involves either replacement of involatile compounds by volatile equivalents or post-column suppression techniques.

In target-compound analysis, the phase-system switching (PSS) approach, based on heart cutting using valve-switching and coupled-column techniques, is successfully used to overcome some of the compatibility problems; following this on-line post-column liquid–solid extraction, a trapping column at the outlet of the analytical column is used to connect HPLC containing nonvolatile buffers and IP agents in the mobile phase to the mass spectrometer. Vrecken extensively discussed the application of post-column liquid–solid extraction in liquid chromatography/thermospray/mass spectrometry (LC/TS/MS) in a book devoted to applications of LC/MS in the environmental field.

With regard to the on-line coupling with ICP/MS, ion chromatography (IC) and ion-pairing chromatography are frequently used for inorganic and organometallic speciation. IC can separate both organic and inorganic charged species and, since it requires low buffer and organic solvent concentrations, unlike IP chromatography, is more amenable for coupling with ICP/MS. In general, liquid chromatography/inductively coupled plasma/mass spectrometry (LC/ICP/MS) based methods require the appropriate choice of chromatographic and plasma conditions to obtain efficient separations and to maintain good detector performance by preventing blocking of the interface or extinguishing of the plasma. Organic solvents used in LC eluents can lessen the performance of plasma MS because of the instability of the plasma to organic vapors and deposition of carbon on the sampling cone and torch. Chromatographic solvents used in normal-phase (NP) partition or adsorption present difficulty for effective plasma interfacing. Reversed-phase (RP) HPLC is most acceptable in LC/ICP/MS experiments; however, as the
percentage of organic eluent components increases, increase of radio-frequency power and the use of water-cooled spray chamber to enhance condensation of volatile solvents is needed. One approach can be microbore HPLC, with lower mobile phase flow-rates and a simpler interface. Mobile phases containing salts can cause short-term signal fluctuation, affect signal-to-noise (S/N) and give a more complex mass spectrum, particularly for \( m/z < 80 \). In addition, the deposition of salts in the nebulizer and on the sampling cone can cause blockage.\(^{19,20}\)

1.3 Tandem Mass Spectrometry and Related Techniques

Interfacing systems such as TS, electrospray/ionspray (ES/IS) and HN/APCI yield soft ionization which can be complemented by recourse to liquid chromatography/tandem mass spectrometry (LC/MS/MS) as realized with the use of a triple-quadrupole system or quadrupole ITs; in the case of the API techniques, collision-induced dissociation (CID) in the interface itself (in-source CID) can be invoked to obtain structural information.

The most common MS/MS operating modes of tandem mass spectrometers are precursor ion scan, neutral-loss or product-ion scan and the selective reaction monitoring (SRM) mode,\(^{21}\) the operational mode chosen being dependent on the analytical information required. Precursor ion, neutral-loss and product-ion scan modes are very selective and thus useful in screening, but they lack the sensitivity necessary for trace analysis. Instead, the use of SRM provides adequate selectivity and sensitivity for the determination of trace compounds in quantitative environmental assay; the choice of a limited number of precursor ion-product IPs to be monitored affords maximal selectivity and better S/N ratio. Both triple quadrupoles and IT analyzers can be used to carry out MS/MS experiments in product-ion mode and SRM mode; with the IT instruments, multiple-stage MS/MS can also be performed, as discussed above (section 1.1).

The selectivity of MS/MS reduces the need for complete chromatographic resolution of individual components; in fact, LC/MS/MS methods may facilitate the identification of substances in unresolved LC peaks, since a full-scan CID mass spectrum is characteristic of the structure of the parent compound. Fast LC/MS/MS analysis reduces the analytical run time thus providing high sample throughput. In addition, in some cases the use of MS/MS equipment allows direct analysis of even complex mixtures without chromatographic separation, making flow injection analysis/tandem mass spectrometry (FIA/MS/MS) helpful for time-saving.

The power of LC/MS/MS as a technique for the detection of analytes of environmental concern has been successfully demonstrated for quantitative analysis particularly in selected reaction monitoring mode.\(^{22}\)

2 ENVIRONMENTAL APPLICATIONS

LC/MS has acquired a role of growing importance in environmental analysis, as is attested by the variety of applications appearing in recent years in this field and by the large number of reviews\(^{23–32}\) and books\(^{33–35}\) on the subject. In a review dealing with the occurrence, sample handling and chromatographic determination of pesticides in the aquatic environment, Barceló\(^{36}\) has discussed the choice of gas chromatography (GC) or LC methods in combination with MS for the unequivocal characterization of pesticides and their breakdown products in environmental samples. In another paper, Barceló\(^{24}\) has reviewed different coupled techniques such as GC/MS, LC/MS and MS/MS for the analysis of polar pesticides, surfactants, PAHs and polychlorinated biphenyls. Advantages and limitations of different LC/MS interfacing systems with reference to selected biological and environmental applications are discussed by the same author.\(^{25}\) Careri et al.\(^{26}\) have highlighted features and limitations of the various LC/MS approaches in an overview dealing with the application of this combined technique for the analysis of pollutants (pesticides, PAHs, inorganic and organometallic compounds, surfactants and dyes). An authoritative review of LC/MS which describes both the interfacing techniques and applications in environmental field is that published by Slobodník et al.\(^{27}\) the application-oriented section of the overview primarily deals with polar pesticides and related substances with emphasis on the on-line and off-line trace enrichment procedures. Chromatographic methods for the analysis of various classes of surfactants (nonionic surfactants, polar aromatic surfactants) in environmental samples have been extensively reviewed in recent papers.\(^{28–30}\) An overview of current analytical methods including LC/MS for the analysis of sulfonated azo dyes in environmental samples has been published by Riu et al.\(^{31}\) More recently, Di Corcia\(^{32}\) has reviewed the state-of-the-art in the characterization of complex mixtures of isomers, oligomers and homologs of surfactants as well as their biointermediates in environmental matrices using LC/MS methodologies.

2.1 Pesticides in Environmental Water Samples

LC/MS is now indispensable in environmental organic analysis and surpasses GC/MS in the determination of polar pesticides; unlike GC, LC is not restricted by compound volatility or thermal lability, from which some pesticides suffer. In this respect, carbamates, triazines

a Nomenclature used by the EC.

(TRIA), phenylureas and their corresponding anilines, and chlorinated phenoxy acids are groups of pesticides for which methods using LC are usually applied, making this technique appealing for multiresidue analysis.

The large number of different pesticides used within the European Community (EC) requires the development of rapid screening multiresidue methods for as many as possible of the most relevant pollutants. In addition, a European Union directive demands methods that allow the verification of the concentration limit of 100 ng L\(^{-1}\) for individual pesticide species in water intended for human consumption, which means that analytical methods should be able to detect pesticides at about one-tenth of this limit or lower, i.e. 10–20 ng L\(^{-1}\).

Table 1 lists pesticides included in the EC priority pollutant list are reported.

In the US system of environmental monitoring, the maximum contaminant levels set by the Environmental Protection Agency (EPA) National Primary Drinking Water Regulations are in the 2–700 µg L\(^{-1}\) range; these guidelines demand limits of 40 and 200 µg L\(^{-1}\) for carbofuran and oxamyl among carbamates in water, whereas limits of 50 and 70 µg L\(^{-1}\) are established for fenoprop (2,4,5-TP) and dichlor phenoxyacetic acid (2,4-D) among phenoxy acid herbicides.

Because it is applicable to a wide range of compounds and is rugged, the TS interface has dominated LC/MS applications for pesticide analysis in environmental samples over the past 10 years. Thermospray mass spectrometry (TS/MS) is mainly used for target compound analysis rather than for the identification of unknown compounds in the environmental field; in fact, TS mass spectra often yield scarce fragmentation and thus lack structural information. To overcome this drawback, several approaches have been used, e.g. different ionization modes (the filament-on mode and the discharge ionization mode) or the coupling of the TS interface with MS/MS. The MS/MS approach is an elegant way of achieving relevant structural information, even though at the cost of a greater complexity of the technique; it is also highly useful for the characterization of unknown pesticide metabolites formed during degradation processes. Complementary information can also be gained exploiting both positive-ion (PI) and negative-ion (NI) modes.

LC/MS with the PB interface is effective in the analysis of medium-polarity low-mass analytes of environmental concern. The combination of retention times, electron impact (EI) mass spectra and isotope distribution patterns for compounds containing naturally occurring isotopes provides excellent information for the unambiguous identification of both target and unknown compounds. The nonlinearity effects at low concentrations and the low sensitivity are the major drawbacks in the quantitative analysis performed by particle beam/mass spectrometry (PB/MS); better quantitative results in terms of linearity and detection limits can be achieved when operating in the presence of mobile phase additives or co-eluting internal standards.

In Table 2 the most important classes of pesticides are briefly summarized, together with the LC/MS interfacing techniques used for their determination and the corresponding references. To date LC/T/MS and LC/PB/MS have been largely replaced by API techniques (ES/IS and atmospheric pressure chemical ionization (APCI); the number of reports dealing with the application of electrospray/mass spectrometry (ES/MS) and HN/APCI/MS in pesticide analysis is rapidly growing. For this reason, this article will cover the most recent application examples in which the API techniques are used. Selected examples of multiresidue analyses of polar pesticides in environmental water samples (drinking water, ground- and surface waters) will be described in the following sections. Polar pesticides (phenylurea, sulfonylurea, phenoxy acid and triazine herbicides, carbamates, phenols, organophosphorus compounds) are considered, since they have become an important part of groundwater monitoring programmes, being the most likely to leach to groundwater.

Solid-phase extraction (SPE) for the preconcentration of the organic micropollutants is usually carried out: in some cases on-line monitoring procedures have been

proposed. The combination of sample treatment by means of SPE with LC/MS in one set-up will be thoroughly discussed in section 3.

2.1.1 Triazines, Phenylureas, Anilides, Carbamates, Organophosphates, Nitrophenols

Column LC with IS or APCI interfaces using MS or MS/MS has been used for the analysis of 17 pesticides belonging to the cited classes in tap and surface waters.\(^{(48)}\)

Surface water samples were spiked with propazine (CAS 139-40-2) and metoxuron (CAS 19937-59-8) as internal standards. Sample aliquots were preconcentrated on PLRP-S (styrene–divinylbenzene copolymer) cartridges. Separations were performed on a C\(_{18}\) column, using acetonitrile–water as the mobile phase. The use of the on-line SPE/LC/API/MS/MS system made it possible to achieve detection limits at low nanograms per liter levels (Table 3). Negative ion acquisition mode was in most cases less sensitive, but organophosphorus compounds and nitrophenols gave adequate signals only in the NI mode. Detection limits obtained with APCI and IS interfaces are similar for the most compounds. However, the IS system appeared to be more prone

to the formation of alkali metal adducts and the ion intensities were strongly dependent on the amount of sodium or potassium deriving from glassware and solvents. LC/APCI/MS in the PI mode appears to be the preferred method for the analysis of the classes of pesticides investigated, except for the organophosphorus compounds (Figure 1).

In MS/MS experiments, the excellent sensitivity of the SIM mode required for trace-level determination of pesticide residues can be combined with the capability in obtaining diagnostic product-ion spectra; Figure 2 shows the APCI and IS product-ion spectra obtained from protonated molecules of pesticides belonging to different classes. The acquisition of MS/MS spectra makes it possible to compile a library of product-ion spectra for the identification of the analytes in real samples.

2.1.2 Acidic Pesticides (Phenoxy Acids, Sulfonylureas, Phenols)

PAES interface has been used for the determination of 18 pesticides, including phenoxy acids, sulfonylureas, phenols, or their degradation products in groundwater samples by means of LC/MS and LC/MS/MS.\(^{146}\)

To obtain satisfactory chromatographic results with these acidic analytes in terms of peak resolution, ion suppression with an acidic mobile phase is necessary. The chromatographic separation was obtained on a C\(_{18}\) narrow-bore column with a gradient elution of methanol–water–acetic acid. Porapak SPE cartridges were used for sample clean-up. Because of the acidic characteristics of the pesticides tested, mass analysis was performed under NI conditions in SIM mode; MS/MS experiments were performed in product-ion scanning mode or SRM mode. The highest sensitivity was achieved using MS and SIM detection. On the other hand, CID MS/MS experiments give a higher degree of confidence in the identification of the compounds by providing structural information.

In Table 4, in addition to the list of the analytes considered, comparison of the instrumental LOD obtained in the two MS detection modes is reported. For most compounds, LOD were three–four times lower using MS with respect to CID MS/MS. LC/IS/MS response was linear in the 5–500 µg L\(^{-1}\) range for most analytes, except for four phenols [DNOC, dinoseb, bromoxynil and ioxynil] and bentazon. The method detection limits (MDLs) were determined on tap water samples spiked with the pesticides, using single MS in SIM mode. The results together with recovery values and precision are quoted in Table 5. The method was then applied to real samples of groundwater, which were first analyzed for the target herbicides using single MS in SIM mode. Positive findings were verified in a subsequent run using MS/MS in SRM mode by detecting diagnostic product ions. An example is reported in Figure 3; the concentration of phenoxy acids determined in the sample were 0.012 µg L\(^{-1}\) of 2,4-D, 0.006 µg L\(^{-1}\) of dichlorprop and 0.010 µg L\(^{-1}\) of MCPA.
2.1.3 Carbamates

Ten carbamate pesticides of widely varying polarity were determined in waters and sediments using LC/IS/MS. Concerning the interfacing conditions, the optimum cone extraction voltage with respect to analyte detectability and identification capabilities was between 15 and 35 V; this parameter is known to affect the sampling efficiencies in API sources. In the mass spectra of most compounds the sodium adduct ion was the base peak. Chromatographic separations were performed on a reversed phase column using methanol–water mixtures as the eluent in gradient mode. The detection limits (S/N = 5–10) obtained with LC/IS/MS were in the 10–60 pg range (Table 6); linearity was checked in the 5–400 µg L⁻¹ range.

Concerning the applications, estuarine water samples were preconcentrated using liquid–solid extraction by passing 2 L of sample on C₁₈-bonded silica disks; the pesticides were recovered by two extractions with 10 mL of acetonitrile; after evaporation, the samples were dissolved in methanol and injected. Figure 4 shows the chromatogram of a surface water sample from the Ebro river and the mass spectrum of the peak eluting at 20 min, which allows the identification of carbofuran at low concentration levels, that is, at a concentration of about 1 ng L⁻¹ in the original water sample. Large-volume injections (500 µL) of tap water spiked at a level of 0.1 µg L⁻¹ of selected carbamates demonstrated the potential of LC/IS/MS with respect to trace-level detectability, making feasible the assay of these pollutants at levels below those of EU drinking water directives.

2.1.4 Organophosphorus Pesticides

Twelve OPP have been determined in groundwater using LC/APCI/MS. In Figure 5 the formulae of the
considered analytes are reported. An automated online liquid–solid extraction procedure was applied on RP (C_{18}) cartridges. Separation was achieved using a C_{8} column and a gradient elution of methanol–water (1% acetic acid). Using APCI/MS with time-scheduled SIM in PI mode, the detection and quantitation limits reported in Table 7 were obtained. At the limit of quantitation (LOQ) concentration level, repeatability (n = 5) ranged from 17 to 25%. Operating in NI acquisition mode, best results were obtained for the parathion group compounds, whereas for the other compounds higher LOQs than those obtained acquiring the PI signals were achieved. Calibration graphs were linear in the range 0.0125–1 ng mL^{-1} for most of the analytes using SIM in PI or NI mode. Figure 6 shows the chromatograms for 100 mL of water samples spiked with 1000 ng L^{-1} of the OPP. The method was validated by analyzing certified samples of groundwater containing organophosphorus derivatives at levels between 10 and 100 ng L^{-1}.

In a recent study, the effects of the probe temperature and of extraction voltage on the fragmentation of the OPP were investigated with the aim of finding the best sensitivity and structural information for identification purposes\(^{(54)}\) compounds having the P=S bond were found to be more thermally stable with respect to those containing the P=O bond. In general, the optimum conditions as regards to flow-rate, probe temperature and extraction voltage were 1.2 mL min^{-1}, 400 °C and 20 V, respectively, even though for some compounds, e.g. trichlorfon (CAS 52-68-6), thermal degradation was observed. For these low thermolabile compounds ES/MS...
is likely the most suitable technique, whereas the other polar OPP and the parathon group are more amenable for LC/APCI/MS analysis.

The examples described prove that LC/MS with IS or APCI interfaces provides instrumental detection limits, which make possible determinations of pesticides in environmental water samples at concentration levels below those of the EC Council directive 80/778/EEC (0.1 µg L⁻¹ for individual pesticide).

### 2.2 Polycyclic Aromatic Hydrocarbons

The presence of PAHs in environmental samples is a legitimate cause for concern, because some PAHs are found to be highly carcinogenic. Widespread in the environment, they originate from the incomplete combustion of organic material from both natural and anthropogenic sources; PAHs have been observed in airborne particulates, coal soot, coal tar, particulate exhaust emissions of diesel- and gasoline-powered engines, marine sediments and water samples.
